Albuquerque, NM 87109

Subject: Revised Ecological Risk Assessment for the Hanover/White Water Creeks Investigation Unit, Chino Mine Investigation Area

Dear Mr. Fox:

Enclosed you will find one hard copy and one CD containing the Revised Ecological Risk Assessment for the Hanover/White Water Creeks Investigation Unit at the Chino Mine Site. The document has been revised to accommodate comments from NMED and Chino Mines through April 7, 2015.

Please do not hesitate to contact me (303-442-0267 x 1001) if you have any questions. Thank you.

Sincerely,
FORMATION ENVIRONMENTAL, LLC

Mark Lewis, Ph.D.
Senior Ecotoxicologist/Risk Assessor

1.0 INTRODUCTION AND PURPOSE

This document presents the results of the Ecological Risk Assessment (ERA) for the Hanover and Whitewater Creeks Investigation Unit (H/WCIU) at the Chino Mine Investigation Area, Grant County, New Mexico (the Site). The Site, located approximately 12 miles southeast of Silver City, includes open pit copper mining facilities, rock stockpiles, leach stockpiles, mineral processing facilities, and tailings impoundments (Figure 1.0-1). Chino Mines Company (CMC) controls approximately 116,000 acres around the mining and mineral processing facilities.

In December 1994, CMC and the New Mexico Environment Department (NMED) entered into an Administrative Order on Consent (AOC) to conduct environmental investigations at the Chino Mine Site and surrounding area as appropriate. The AOC requires that a Remedial Investigation/Feasibility Study (RI/FS), including human and ecological risk assessments (ERAs), be completed for each of the following Investigation Units (IUs):

- Lampbright Draw;
- Hanover Creek;
- Whitewater Creek;
- Smelter;
- Hurley Soils; and
- Tailing Impacted Soils.

For practical and logistical reasons, the Hanover Creek and Whitewater Creek IUs, and the Smelter and Tailing Soils IUs have been combined for performing the RI/FS. To date, the RI/FS is complete for only the Hurley Soils IU.

CMC and NMED agreed to conduct a baseline ERA (BERA) for the combined IUs based on suggestions that an ERA could be more effectively conducted on a Sitewide basis. An Ecological IU was designated for this purpose and added to the AOC in December 1995 (NMED 1995). The Ecological IU encompasses areas of the other IUs that may contain ecological resources and may be affected by contaminant releases (NMED 1995).

The Sitewide BERA focused on areas of the Site that may have been affected by historical releases of contaminants from mining and milling operations. In accordance with the AOC, current operational sources that are regulated under state or federal permits would not be considered in the risk assessment process, but areas affected by historical releases occurring from the sources prior to permitting are to be addressed if data from the RIs indicate contamination.

The Sitewide BERA, completed in December 2005 (NewFields 2005), was conducted in accordance with United States Environmental Protection Agency (USEPA) guidance for ERAs at Superfund (Comprehensive Environmental Response, Compensation and Liability Act of 1980 [CERCLA]) sites (USEPA 1992, 1997). While the Chino Mine Site is not a Superfund site, the intent of the AOC is to produce CERCLA-like investigations and remedies. General guidance on conducting ERAs (USEPA 1998) was used in planning and development of the risk characterization approach for the BERA and in the terminology used in the Sitewide BERA Report (NewFields 2005).

Because the RI had not been completed when the BERA was designed and conducted, the nature and extent of contamination in the IUs had not been fully characterized. Therefore, the BERA design focused on identifying chemicals of potential concern (COPCs) for ecological receptors, characterizing stressor-response relationships for key COPCs, and developing risk-based tools for further evaluating ecological risk in individual IUs as more complete nature and extent characterization became available from the RI. As described in Section 1 of the Sitewide BERA Report (NewFields 2005), and detailed in Technical Memorandum No. 1 (TM-1) (Schafer 1999a), the Chino ERA study design was based on assessing risk along a gradient of contamination, indicated by soil copper concentrations and pH described in the RI Background Report (CMC 1995). The tools provided in the Sitewide BERA were intended to facilitate implementation of the ERAs for each IU as additional RI data became available. The IU-specific ERA for the H/WCIU focuses on the risk characterization in terms of Sitewide contribution to risk, to help focus risk management decisions within this IU.

The H/WCIU is assumed, in this document, to include all areas within Hanover and Whitewater Creeks extending from the northern AOC boundary at Highway 152 (Figure 1.0-1) downstream to the southern extent of sampling approximately eight miles south of Tailings Pond #7 (TP-7). Also included in this risk assessment are portions of Whitewater Creek from the southern AOC boundary to the San Vicente Arroyo and a small area east of Whitewater Creek where it appears that the creek broke out of its channel and deposited sediment in a side channel. The H/WCIU does not include areas that are part of the Hurley Soils IU, Smelter and Tailings Soils IUs, Lampbright Stockpile IU or the operational areas of the Site.

1.1 Summary of Problem Formulation

A full problem formulation discussion, including a history of releases and overall ecology of the AOC area, is presented in the Sitewide BERA Report (NewFields 2005). The initial problem formulation used to develop the overall study design for the Chino ERA is presented in TM-1 (Schafer 1999a). A detailed discussion of the IU and history is provided in the Hanover and Whitewater Creeks Phase I RI Report (Golder 2000).

The potential chemical stressors at the Site consist primarily of metals, associated inorganics (e.g., sulfate), and acidic pH. The Sitewide BERA identified potentially complete exposure pathways that were used to evaluate the risk of direct effects on ecosystem components from chemical stressors associated with the Site. The Sitewide BERA also included indirect effects such as a loss of nesting sites or prey base.

1.1.1 Site Description

Major topographic features in the AOC investigation area include the Cobre Mountains and the San Vicente Basin. Erosion of the plateau surface in the Cobre Mountains southeast of Bayard has resulted in a series of even-crested, southward-sloping ridges that gradually become low hills. The topographic high within the AOC investigation area is approximately 7,700 feet above mean sea level (amsl).

The San Vicente basin is a broad lowland that extends northward from the Mimbres Valley. The basin terminates against the Big Burro and Little Burro Mountains on the west, Silver City and the Pinos Altos ranges on the north, and the Cobre Mountains on the east. The slope of the terrain is from these mountains toward the San Vicente Arroyo. The San Vicente Basin is characterized by several dry, sandy washes and gullies. Elevations in this area of broad plains range from about 5,700 feet near Hurley to 4,500 feet at the confluence of Whitewater Creek with the San Vicente Arroyo.

The geology of the H/WCIU is described in detail in the Hanover and Whitewater Creeks Phase I RI Report (Golder 2000). The soils and sediments in the H/WCIU are largely derived from mineralized sources present in the headwater portions of the watershed. Golder (2004) conducted a background sediment investigation in order to determine pre-mining metals concentration in H/WCIU soils/sediments derived from the various upgradient mineralized materials. By observing vertical soil profiles, Golder (2004) provided indications of natural background levels derived from copper-rich materials in the Santa Rita Stock and the Hanover-Fierro Stock.

Hanover and Whitewater Creeks flow through areas of alligator juniper and oak woodland vegetation communities in the northern portions of the drainage. Both creeks also flow through residential and historical mining areas in the upstream portions of their drainages. South of Bayard, Whitewater Creek flows through primarily mesquite/mixed-grama shrubland and fluvial forests. From the south end of the mine facilities to the San Vicente Arroyo, the vegetation community grades into a mixed grama herbaceous community. Smaller creeks that drain the higher south-facing slopes west of Whitewater Creek generally flow through mountain mahogany shrubland in the higher elevations (above about 6,000 feet amsl) in the northern sections of the IU downward into the mesquite/mixed grama habitats in the lower elevations of the Site (Figure 1.1-1).

The lateral extent of the H/WCIU was based on the fluvial geomorphological features associated with the current and historic flowpaths of Hanover Creek and Whitewater Creek. Vegetated (or potentially vegetated) fluvial overbanks and terraces identified by Golder (2000) were included in the analysis of exposure to terrestrial receptors including the vegetation and faunal receptors. Active channel sediments and point bars were not included in the risk analysis for wildlife and vegetation because these areas lack stable vegetation that would be used by wildlife in ways that would result in important exposure pathways such as ingestion.

Aquatic habitats in the H/WCIU are generally limited due to lack of persistent sources of water. Temporary pools develop from precipitation events or seasonally elevated discharges of shallow groundwater and provide temporary habitat for amphibians and aquatic invertebrates that may utilize the pools for reproduction. In some locations, such as Bayard Canyon and the James Canyon impoundment, more permanent pools exist due to persistent groundwater seeps or local springs.

1.1.2 Overall Conceptual Site Model and Study Design

Conceptual Site Models (CSMs) have been used to describe the Chino Mine Site in several documents (CMC 1995; Schafer 1999a, 1999b; Golder 2000). The potentially complete exposure pathways and associated potential effects used to guide the design and analysis of the H/WCIU ERA are shown in the Chino Mines ERA CSM (Figure 1.1-2), which is essentially unchanged from the CSM used in the Sitewide BERA.

For riparian areas, the primary contaminant sources and release mechanisms are fluvial transport and to a lesser extent, smelter emissions and windblown tailings (Figure 1.1-2). Prevailing winds tend to be from the northwest (CMC 1995). Therefore, soils in areas south and east of the smelter and the tailing impoundments are likely to be most affected by dryfall from these aerial sources. The entire system is likely to be affected due to fluvial transport of materials from mining areas to the north and air/wind deposited materials adjacent to and downstream of the smelter and tailings impoundments. Although the drainages east of Whitewater Creek may have been directly affected by dryfall, they may also have been affected by the downgradient erosional transport of impacted soils and tailings into the drainages. Through this mechanism, COPCs could concentrate in fine materials deposited on soils along the drainages, as well as in sediments in the active channel.

As noted above, when the BERA commenced, Phase I RIs had not been completed for any of the IUs. Therefore, the nature and extent of contamination had not been fully characterized. As a result, the overall goals of the analysis were to determine whether Site conditions represent a risk to ecological receptors and, if so, to develop risk criteria that can be used to assess the potential for risk in areas that had not yet been characterized through the RI process.

The overall technical approach to sampling and risk analysis was based on a modified "gradient" approach (USEPA 1997) in which a suite of analyses was performed at sites selected to represent the range of observed copper concentrations and pH. Copper was identified as a key COPC based on results of the Screening-Level Ecological Risk Assessment (SLERA) and the Phase I Ecological Remedial Investigation (ERI) (WCC 1997). The general objective was to identify a combination of COPC concentrations, pH, and other environmental factors that are protective of assessment endpoints, and then to apply these findings to future data on nature and extent of contamination.

A total of 34 sampling locations were originally identified for the BERA, including locations generally along a west-east gradient of copper concentrations and pH observed east of the former smelter location, and other locations along the Hanover and Whitewater Creek corridor, as well as other parts of the Site that represented various copper and pH conditions. A reference area was identified in a portion of the San Vicente Arroyo approximately 6 miles southwest of Hurley. The reference area was not intended as an ideal reference area in the traditional sense. Rather, it was intended to represent a condition in the gradient approach in which copper was relatively low and soil pH was high, compared to the study area. Synoptic sampling of surface and subsurface soil, vegetation, invertebrates, and small mammals was conducted at each location. Phytotoxicity testing was conducted on soils from each of the 34 BERA locations.

1.1.3 Assessment Endpoints

Assessment endpoints are explicit expressions of the ecological resources that risk managers wish to protect for a given site (USEPA 1992, 1997, 1998). The BERA problem formulation identified a set of assessment endpoints based on ecological relevance, potentially complete exposure pathways, taxonomic groups that may be sensitive to chemical stressors and are potentially exposed, and site management goals (Schafer 1999a).

The assessment endpoints are accompanied by “risk questions” described by USEPA (1997) as the questions the ERA will attempt to answer regarding whether or not assessment endpoints could be adversely affected by exposure to COPCs. The risk questions form the basis for identifying the specific analyses to be conducted and the data needed to perform the analysis. In some cases, risk questions may be stated as risk hypotheses (USEPA 1998), which are then used to identify the data collection and analysis to be performed. Evaluation of risk hypotheses is not necessarily equivalent to formal statistical tests of null hypotheses (USEPA 1998).

The assessment endpoints and risk questions used to guide the development of the Sitewide BERA are presented in Table 1.1-1. The assessment endpoints can be broken down into three main categories with subcategories as follows:

Terrestrial Vegetation as Wildlife Habitat

- Ephemeral drainages
- Upland sites

Terrestrial Wildlife

- Herbivorous, insectivorous and omnivorous birds
- Raptors
- Herbivorous, granivorous and omnivorous small mammals
- Ruminants
- Mammalian predators

Aquatic Receptors

- Amphibians
- Aquatic invertebrates and fish community

1.1.4 Sitewide BERA Conclusions

As noted above, the Sitewide BERA study design was based on assessing risk along a gradient of contamination, indicated by soil copper concentrations and pH described in the RI Background Report (CMC 1995) and along the riparian areas of Hanover and Whitewater Creeks. The Sitewide BERA assessed potential risks to each of the assessment endpoints at the CMC Site. Some potential for risk was identified for several receptors evaluated. The conclusions reached in the Sitewide BERA regarding potential risks are summarized below.

Contaminant Distribution with Respect to Exposure Potential

1) Metal concentrations have apparently increased, and soil pH has decreased as a result of mining operations in some areas of the Site; metal concentrations are most elevated in surface soils.

2) Due to depressed pH, the bioavailable fraction of metals has increased, and metal exposure has also apparently increased.

3) A wide range of exposure conditions exist at the Site, corresponding to both elevated metal concentrations and depressed pH.

4) A wide range of exposure conditions exist in a demonstrable gradient with distance from the smelter and tailings impoundments (especially southeast of the smelter and the old Lake One area).

Vegetation

Overall trends identified from results of the Sitewide BERA analysis indicated that:

1) Trends in upland vegetation community structure and composition were observed between study and reference area locations, and among study area locations; locations closest to the sources and containing the highest concentrations tended to have lower richness and cover than areas farther away from the sources;

2) Ephemeral drainage communities tended to have richness and cover similar to that of the upland reference areas. However, communities may not be comparable because of the wide range of conditions among ephemeral drainages; and

3) Phytotoxicity testing indicated that soils from areas of the Site closest to the mine facilities were more toxic than reference area soils and more toxic than study area locations more distant from the mine and mineral processing facilities.

Use of the term ephemeral as it applies to terrestrial habitat in drainages corridors does not imply classification of the stream segments by the State of New Mexico for purposes of assigning distinct protections under the New Mexico Water Quality Act (see 20.6.4.97-99 NMAC). Where aquatic habitat or surface water quality standards are discussed, these stream segments are referred to as ‘non-perennial’.

The stressor response analysis presented in the Sitewide BERA evaluated whether or not the potential exposure to terrestrial plants from Site soils was correlated with the effects on community structure and (laboratory-tested) phytotoxicity. The analysis indicated that cupric ion activity (expressed as the negative logarithm of cupric ion activity [pCu^{2+}]), a measure of available copper, was the best overall predictor of field and laboratory vegetation response variables. Several measurement endpoints including community species richness, total canopy cover, stem weight and length (laboratory studies), and root weight and length (laboratory studies), were more highly correlated with pCu^{2+} than with any other measure of metal concentration (Table 1.1-2). Other measures including seedling emergence, survival and the number of rhizobium containing root modules (alfalfa) were more highly correlated to water-soluble copper, but in all cases pCu^{2+} was one of the most highly correlated values for those measures as well. Bioavailable copper was identified as the risk driver for potential effects to terrestrial vegetation in the Sitewide BERA.

The Sitewide BERA concluded that elevated copper and other metals, combined with depressed pH, have led to higher risk of phytotoxicity for some areas of the Chino Mine site, particularly those areas closest to the smelter and tailings impoundments such as ERA-01, ERA-02, ERA-03 and ERA-07 within the Smelter and Tailings Soil IUs (S/TSIU). The effects are highly dependent on soil pH; some locations within the S/TSIU (ERA-11, ERA-12, ERA-13, ERA-14 and ERA-15) had elevated copper concentrations, but relatively high pH and exhibited little or no evidence of phytotoxicity in field measurements and/or laboratory exposure studies.

The Sitewide BERA also indicated that other COPCs could contribute to toxicity under low soil pH conditions, including cadmium, lead and zinc, which are elevated at several riparian areas in the upstream portion of the H/WCIU primarily associated with historic mining operations. Additionally, non-Site COPCs such as aluminum and manganese could also be toxic when present at natural concentrations in soils where pH is less than 5.0. Physical conditions and historic land use (i.e., cattle grazing) also affect vegetation at the Site and could be responsible for some of the variability observed in the plant communities, and could also affect overall wildlife habitat quality.

The pCu^{2+} was highly predictable from soil pH and total copper concentration. The models derived in the Sitewide BERA are presented in Table 1.1-3 along with the r-squared values from the regression analyses used to create the models. To help guide the vegetation risk characterization, pCu^{2+} levels corresponding to a range of effects were identified based on graphical analysis. The level of cupric ion activity is expressed as the negative logarithm of the activity (i.e., pCu^{2+}), similar to the way in which hydrogen ion activity is expressed as pH. Therefore, higher pCu^{2+} values indicate *lower* activity, and lower pCu^{2+} values indicate *higher* activity. Higher activity is generally associated with greater risk of toxicity.

Two benchmarks for vegetation risk were identified: a *de minimus* (i.e., negligible) effects level (DEL; $pCu^{2+} > 6$ to 7) above which no ecologically significant adverse effects are expected, and a probable effects level (PEL; $pCu^{2+} \leq 5$) below which the detection of adverse effects is considered probable. Adverse effects are possible for pCu^{2+} values between the DEL and PEL, but the ecological significance of such effects is less certain. The DEL and PEL are used in the H/WCIU ERA to characterize potential risks to the terrestrial plant community.

Terrestrial Wildlife

A detailed assessment of risks for all terrestrial wildlife receptors was provided in the Sitewide BERA. The conclusions drawn indicate that risks to wildlife receptors appear to be relatively restricted to the most contaminated areas of the Site immediately east of the smelter and northernmost tailings impoundments (within the S/TSIU) and at some locations along the Hanover and Whitewater Creek corridor (within the H/WCIU). Risks to ground-feeding birds appeared to be of potentially greatest concern based on risk from copper intake from ingested soils and food as well as cumulative risk from intake of other COPCs. Risk to small mammals was of second-greatest concern, but was substantially less than that estimated for ground-feeding birds. Individuals of larger and more mobile receptors such as ruminants, mammalian predators and raptors appeared to be at relatively low risk. Overall, the Sitewide BERA indicated that local populations inhabiting the AOC or within sub-areas of the AOC could be affected in localized areas. No effects to regional populations of wildlife were predicted primarily because of the extensive areas adjacent to the Site that provide similar habitat.

The Sitewide BERA provided a range of soil screening levels (SSLs) for use in assessing copper risk to the small ground-feeding bird receptor. These values were utilized in the draft H/WCIU ERA document (NewFields 2008). Data collected subsequent to 2008 and negotiations conducted between NMED, USEPA and CMC resulted in revisions to the benchmarks. The revised benchmarks were used in this assessment and are discussed in more detail in Section 3.

Risk estimates specific to H/WCIU are provided for all COPCs evaluated in the receptor-specific detailed analysis portion of the Sitewide BERA. Based on the revised benchmark effort, exposure models for the small ground-feeding bird have also been modified from the BERA in order to assess exposure to non-copper COPCs. For all other receptors and COPCs, the exposure models and toxicity reference values (TRVs) used in the Sitewide BERA are unchanged in this risk assessment.

Aquatic Life

Only surface water and sediment data were available for use in the Sitewide BERA. The report generally concluded that potential risks from cadmium, copper, lead and zinc were predicted along the Whitewater Creek corridor and in Bolton Draw. However, it was noted that the habitat in these areas was highly limited, indicating that aquatic populations are also likely limited by the quality of aquatic habitat available.

Additional data were collected as part of the Phase 1 H/WCIU RI in order to address deficiencies in the spatial coverage of surface water and sediment data within Hanover Creek, Whitewater Creek, and several of the tributaries associated with Whitewater Creek. These data are used in this report to further characterize the potential for aquatic risk within the H/WCIU.

1.1.5 COPCs Evaluated in the H/WCIU ERA

The Sitewide BERA identified a list of COPCs that were assessed for each of the three main categories of assessment endpoints. These chemicals were identified as COPCs in the Sitewide BERA via the SLERA process that conservatively compared upper-bound concentrations to risk-based toxicity values. The COPCs evaluated in the Sitewide BERA are listed below and constitute the list of COPCs that were also evaluated in the H/WCIU ERA:

Terrestrial Vegetation as Wildlife Habitat

- Copper
- Hydrogen ion activity (pH), as a factor modifying copper toxicity

Terrestrial Wildlife

- Cadmium
- Chromium
- Copper
- Lead
- Molybdenum
- Selenium
- Zinc

Aquatic Receptors

- Cadmium
- Copper
- Lead
- Zinc

1.1.6 Data Used in the H/WCIU ERA

Data specific to the H/WCIU were collected or reviewed as part of the RI Background Report (CMC 1995), Hanover and Whitewater Creeks Phase I RI Report (Golder 2000), the Ecological RI (Arcadis JSA 2001), the sediment background investigation (Golder 2004), and recent data collected specifically to fill data gaps related to the H/WCIU ERA (Golder 2002, 2003, 2007, 2008). The most recent RI dataset (Golder 2008) was collected based on data needs identified for characterizing the nature and extent of contamination for the ERA. The primary ERA data needs were identified to (1) fill spatial data gaps for soil/sediment in the H/WCIU, particularly in overbanks in Hanover Creek, (2) obtain tissue samples (seeds, foliage and invertebrate) in H/WCIU overbank areas, and (3) obtain additional water samples from streams and tanks (i.e., stock ponds). The ERA risk analysis includes all historical data evaluated in the BERA, and the data collected as part of the H/WCIU RI.

Data from shallow soil (0 to 6 inches below ground surface [bgs]), shallow sediment (0 to 6 inches bgs), surface water, above-ground foliage, seed head, and terrestrial invertebrate samples collected from a number of investigations were used to prepare the H/WCIU ERA, as shown on Figures 1.1-3 through 1.1-13. (Refer to Section 3, Figures 3.2-1 through 3.2-7 for maps with foliage, seed head, and invertebrate sampling locations.)

The following bullets provide an overview of the samples used in the H/WCIU ERA. Samples were collected from various investigations within the IU between 1995 and 2008. Unless otherwise noted, soil and sediment samples were collected from the 0 to 6 inch bgs depth interval and sieved to include the less than 2000 micron (µm) size fraction. The soils data from the less than 2000 µm size fraction were applicable for use in the ERA and are consistent with methodologies used in the Sitewide BERA. The smaller size fraction sampled for the human health soil samples as part of the Phase I RI represent the size fraction that would be most likely to adhere to human skin. While dermal exposure to wildlife receptors may be a pathway of exposure, it is generally considered to be of lower concern than ingestion pathways evaluated quantitatively in the Sitewide BERA. Soil samples from the larger size fraction are more likely to represent soils that wildlife receptors may be exposed to when grazing, browsing, or burrowing. At each summer rainfall pool location, samples were collected for (1) evaluation of the total metals fraction and (2) evaluation of the dissolved metals fraction after filtration at 0.45 µm.

- Background Remedial Investigation Report (CMC 1995)

  Sediment samples were collected from active channel areas, tributaries, and tin can operations. Soil samples were collected from overbank deposits and composite soil samples were collected from yards in residential areas.

- Phase I RI (Golder 2000)

  Sediment samples were collected from active channels and tributaries. Soil samples were collected from channel bars, overbank deposits, and terraces. Analytical results were obtained for soil/sediment in the less than 250 µm and 250-2000 µm size fractions. A mass-weighted average was calculated for the less than 2000 µm fraction using the results from the other two fractions. Eleven summer rainfall pool samples were also collected as part of the Phase I RI.

  Eleven samples (seven sediment and four soil) were collected following a tailings spill event in November of 1999 from the same locations where the Phase I RI samples had been collected. These samples were collected and analyzed following the same procedures as the Phase I RI samples, and the data were used in place of the pre-tailings spill samples (Golder 2000).

- Ecological RI (Arcadis JSA 2001)

  Nine soil samples were collected from overbank deposits in ephemeral drainages within the H/WCIU for use in the ERA.

- Technical Memorandum: Investigation of the Side Channel on Lower Whitewater Creek (Golder 2002)

  Channel transect composite sediment samples were collected from the Side Channel in November/December 2001. A subset of three sediment samples were subject to a modified Synthetic Precipitation Leaching Procedure (SPLP) and water soluble metals data were generated.

- Technical Memorandum: Supplemental Investigation of Lower Whitewater Creek (Golder 2003)

  Channel transect composite samples were collected from Lower Whitewater Creek in June 2003. Several soil samples were collected from upland areas and overbanks. A total of 16 sediment samples were collected from active channel areas. A subset of nine samples was subjected to a modified SPLP and water soluble metals data were generated.

- Sediment Background Investigation (Golder 2004)

  Sediment samples were collected to determine background concentrations of Site COPCs.

- Technical Memorandum: Summer Rainfall Pool Sampling (Golder 2007)

  Samples were collected from summer rainfall pools throughout the H/WCIU in September 2006.

- Technical Memorandum: Data to Support Ecological Risk Assessment (Golder 2008)

  In September 2007, soil samples were collected from overbank deposits and vegetated channel bars, and channel transect composite sediment samples were collected from active channel areas. A subset of six active channel sediment samples were subject to a modified SPLP and water soluble metals data was generated. Eight additional summer rainfall pool samples were also collected.

  NewFields collected composite biota samples from locations in the H/WCIU in September and October 2007. Above-ground foliage, seed head, and terrestrial invertebrate samples were collected. In addition, NewFields collected five sediment grab samples from a visually impacted area of Lower Whitewater Creek.

- Terrestrial Invertebrate and Copper Bioavailability Study; Smelter/Tailings Soils Investigation Unit (Arcadis 2010)

  CMC submitted a technical memorandum addressing concerns related to changes in uptake of copper into invertebrate tissues in the S/TSIU related to an atmospheric deposition of calcium carbonate (the ‘white rain’ event) which took place in January, 2008 over the entire Site. The effect of the rain was an increase in soil pH over a wide area. The pH increase coupled with several additional technical issues related to the calculation of the copper SSL prompted CMC to collect collocated soil and terrestrial invertebrate samples at 17 locations (14 of them original BERA sampling locations). CMC proposed a revised SSL for copper. The data collected for this task were not directly used in this report, however, the resulting changes to the bioaccumulation model and revised SSLs are used.

The local sources of contamination, transport pathways, and physical features differ along the H/WCIU, therefore, all discussions of data within the H/WCIU are presented by physical reaches as identified by Golder (2000, 2004). Because the physical reaches were not originally identified based on ecological exposure, several have been combined and several additional assessment areas have been defined.

Data were grouped as follows:

- Physical Reach 1 – Hanover Creek;
- Physical Reach 2 – Whitewater Creek upstream of Hanover Creek to Bayard;
- Physical Reach 3 – Whitewater Creek from Bayard to Hurley;
- Bayard Canyon – Samples collected within Bayard Canyon;
- Physical Reach 4 and 5 – Whitewater Creek from Hurley to downstream of TP-1;
- Physical Reach 6 and 7 – Whitewater Creek from TP-1 to TP-7;
- Physical Reach 8 and 9 – Whitewater Creek from TP-7 to downstream of Highway 180;
- Side Channel – Whitewater Creek side channel area south of TP-7; and
- Lower Whitewater – Whitewater Creek south of Highway 180 to near the San Vicente Arroyo.

All available soil/sediment and surface water sample locations are shown in Figures 1.1-3 through 1.1-13. The data resulting from the H/WCIU sampling are presented in Appendix A (Tables A-1 through A-6). As noted above, data from the ERI (within the boundaries of the H/WCIU) are also included in this assessment, as well as samples from the Sediment Background Investigation (Golder 2004).

Physical Reach 5 has been dramatically altered in terms of channel configuration, watershed area, and potential ecological habitat to the point that the remnant channel sections that still persist function more as stormwater runoff channels. In addition, they are hydrologically disconnected from former seasonal flows within Whitewater Creek and subject only to highly ephemeral flows from the inactive tailings impoundments. Due to the extent of diversions, the expected potential ecological habitat in Physical Reach 5 has been reduced significantly, and would be more appropriately managed under the STSIU if not covered by a Discharge Permit.

The pertinent samples within Physical Reach 5 are shown in Figure 1.1-6. Samples ERA-23, ERA-26, and U03-ER005 should be considered within the S/TSIU while samples U03-5032, U03-5033, U03-1500B, U03-5034, and U03-3500 are within the pre-diversion Whitewater Creek channel and will not be considered further in this assessment. Finally, samples U03-5500, U03-5501, U03-5502, and U03-5503 were collected within the James Canyon reservoir which is considered by NMED as an operational area under Discharge Permit 214 and similarly will not be considered further in this assessment. As a result, risks from Physical Reach 5 are not discussed further in this document.

1.2 Organization of the H/WCIU ERA Report

This H/WCIU ERA relies heavily on detailed problem formulation presentations provided in the Sitewide BERA and TM-1, while focusing on the results of the H/WCIU RI sampling and the re-assessment of ecological risk in light of the greater resolution provided by the additional data. Risk analysis is grouped by assessment endpoint as follows:

- Section 2: Risk Analysis for Vegetation in the H/WCIU;
- Section 3: Risk Analysis for Terrestrial Wildlife in the H/WCIU;
- Section 4: Risk Analysis for Aquatic Receptors in the H/WCIU;
- Section 5: Uncertainties; and
- Section 6: Conclusions and Recommendations.

2.0 RISK ANALYSIS FOR VEGETATION IN THE H/WCIU

This section presents the H/WCIU risk analysis for the terrestrial vegetation assessment endpoint. As discussed in the Sitewide BERA, the primary contaminant sources in the H/WCIU are from fluvial transport of COPCs from source areas associated with historical mining operations, and dryfall directly from smelter emissions and windblown tailings (Figure 1.1-2).

The ephemeral drainage locations sampled as part of the ERI (Arcadis JSA 2001) were all in areas classified as fluvial forest shrubland alliance. However, the vegetation alliance bordering the ephemeral drainages is varied. Sites in portions of Whitewater Creek within the Smelter and Tailing Soils IU were largely bordered by mesquite/mixed grama areas, whereas more northern locations (ERA-28, ERA-29, ERA-30, ERA-34) were bordered by alligator-oak woodland or alligator-oak /grama Woodland communities. At most of the locations, trees and tall shrubs of the fluvial forest shrubland alliance were mainly restricted to the drainage bottoms, and the boundaries with adjacent upland communities were not well delineated.

As described in the Sitewide BERA and TM-1, the primary exposure pathway for terrestrial plants to COPCs in H/WCIU soil/sediment is through absorption or direct contact of roots with contaminated soils. The effects of Site conditions on the mobility and bioavailability of COPCs in soils are important considerations in the risk assessment. The geochemical behavior of metals and inorganics following deposition onto soils and sediments greatly affects their mobility, speciation, and bioavailability. Important geochemical reactions occur in soils that strongly affect the speciation of metals and the ease with which they are assimilated by plants. Most important is the pH of the immediate environment, and secondarily is the concentration of dissolved ligands. In acidic pH, most metals occur in solution as the free metal ion (e.g., Cu^{2+} or Pb^{2+}). As pH increases, the free metal ion bonds with dissolved ligands to form charged and uncharged dissolved complexes of varying stability and bioavailability (e.g., $CuSO_4^o$, $CuHCO_3^+$, $CuCO_3^o$, Cu-organic). Stable complexes exhibit substantially lower bioavailability, and hence lower toxicity, than weak complexes or the free metal ion. Depending on the pH, the proportion of metal complexes may comprise a significant portion of the total metal load in a system. Consequently, the total content of metals in soil and water can be less important than the abundance of the speciation and bioavailable fraction present.

Other factors that affect speciation and mobility include the presence of iron, aluminum, and manganese oxyhydroxides, organic carbon content, and clay content. These phases act as strong sorbents that remove metals from solution and render them unavailable to biota. For example, copper forms strong complexes with organic carbon compounds and forms relatively insoluble carbonate or oxide compounds above a pH of 5.5. As such, copper may be largely bioavailable in acidic soils that are low in organic carbon, and unavailable in neutral pH, clayey soils rich in carbonate and organic matter.

In the presence of sufficient soil alkalinity (usually as calcium carbonate) typical of New Mexico soils, metals such as cadmium, lead, and zinc can be removed from solution as carbonate minerals, such as otavite ($CdCO_3$), cerussite ($PbCO_3$), or smithsonite ($ZnCO_3$). Other inorganic constituents such as the metalloids arsenic, selenium, and molybdenum tend to form negatively charged oxyanions in soil solutions (e.g., AsO_4^{2-}, SeO_4^{2-} and MoO_4^{2-}) that are relatively immobile when pHs are less than 7, but become mobile under slightly alkaline pH (pH>7). Most of the metal COPCs at the Chino Mine Site are very susceptible to adsorption to aluminum, iron, and manganese oxy-hydroxide solids ("sesquioxides") in the soil zone. This is an extremely important removal mechanism because sesquioxides are abundant in New Mexico soils, and adsorption to these solids occurs even when COPC levels are below that required for metal precipitation.

Thus, metal bioavailability is dependent upon a complex combination of mineral content and pH of soils in affected areas. However, the overall most important factors for a given soil and contaminant type tend to be the total concentration and the pH. The vegetation risk analysis focused on these variables for assessing potential phytotoxicity and effects on vegetation.

2.1 Assessment Endpoint and Objective

The quality of vegetation within the ephemeral drainages associated with H/WCIU as wildlife habitat is the assessment endpoint addressed in this section (Table 1.1-1). Vegetation is critical as a food source and as physical habitat for wildlife. Various plant species have been shown to be sensitive to metals, including copper, and acidic pH in soils by exhibiting toxic responses when exposed. Metal toxicity to vegetation can alter the plant community composition and structure, which can result in decreased wildlife habitat and range quality. The assessment objective was to assess the risk that increased metal concentrations and depressed pH due to mine and mineral processing activities could affect adversely vegetation at the Site.

2.1.1 Bioavailable Copper

Bioavailable copper (as pCu^{2+}) appeared to be the best predictor of potential phytotoxicity in the Sitewide BERA. The predicted pCu^{2+} in each of the H/WCIU channel bar or overbank sediment samples was calculated using the 2-variable (pH and total copper) model for ephemeral drainages (Table 1.1-3). Predicted pCu^{2+} values are presented in Table 2.1-1.

The predicted pCu^{2+} is higher than 7 in 49 of 105 total H/WCIU surface soil samples (<2000 µm size fraction) collected from bar and overbank locations (excluding active sediment channel samples) throughout the IU. Values of pCu^{2+} greater than 7 indicate a lack of potential toxicity, while values less than 7 indicate increasing potential for toxicity. The predicted pCu^{2+} was within the DEL range (pCu^{2+} 6 to 7) in 14 samples while an additional 6 samples were between the minimum DEL (6) and the PEL (5). The potential for effects in the PEL range is unknown but should be considered to be greater than those soils with pCu^{2+} in the DEL range. Thirty-five samples had pCu^{2+} values predicted to be lower than the PEL. These areas represent the highest risk of adverse effects from copper and depressed pH, and some level of effects to community structure and/or plant growth is expected in these areas. As shown in Figures 2.1-1 through 2.1-8, pCu^{2+} values are predicted to be lowest (i.e., highest risk of toxicity) in Physical Reaches 3 through 8 in Whitewater Creek from Bayard to the southern end of the tailings impoundments, with the exception of Physical Reach 4 which contains only one sample at a predicted pCu^{2+} equal to 7.45.

Whitewater Creek in both the side channel and in several areas of lower Whitewater Creek is not highly channelized and sedimentation occurs over wide areas during flow events. While samples collected from these areas are labeled as active channel sediments, the sediments are likely very infrequently inundated and more closely resemble overbank terrace sediments. Estimated pCu^{2+} values from those sample locations are also provided in Table 2.1-1 and are shaded grey.

As previously discussed in Section 1.1.6, a significant area-wide ‘white rain’ event took place in January 2008. During this event, precipitation laden with a white milky substance, later identified as calcium carbonate, fell over the entire Chino Mine Site, including H/WCIU. The white rain event resulted in increased pH in soils within both the S/TSIU and H/WCIU (CMC 2010). CMC has implemented a pH monitoring plan in the S/TSIU to help assess the permanence of the pH increase. After the fourth year in a five-year study, measured pH values in soils have consistently either risen or remained similar in measured areas (Arcadis 2014).

2.2 Community Metric and Laboratory Phytotoxicity Testing

Results of the community assessment and laboratory phytotoxicity testing were presented in detail in the Sitewide BERA. No additional data for either of these two measures were collected as part of the H/WCIU RI. The results of community and laboratory testing as they relate to the H/WCIU are summarized in this section.

Statistical analyses in the Sitewide BERA indicated significant differences among phytotoxicity test endpoints of perennial ryegrass and alfalfa grown in Site soils compared to both reference area soils and laboratory control soils. There were also significant differences in toxicity endpoints among H/WCIU locations, which were correlated with bioavailable copper concentrations predicted by pCu^{2+} calculations and water-soluble copper (Table 2.1-1 and see BERA Table 2.2-3 for more details). Compared to controls, seedling emergence and survival was significantly reduced for for ERA-29 (alfalfa emergence only), but no community effects were observed for this location (Table 2.2-1). No suitable reference areas for the ephemeral areas of H/WCIU were identified for the BERA, and so no quantitative comparisons between offsite and affected areas in the H/WCIU are available.

2.3 Terrestrial Vegetation Conclusions

The overall conclusions regarding risk to the vegetation assessment endpoint remain unchanged from the Sitewide BERA. Copper (and other metals) concentrations are elevated above the background range identified for the H/WCIU corridor (95th upper confidence limit [UCL95] = 183 milligrams per kilogram [mg/kg]; Golder 2004) in most of the overbank and vegetated bar sampling locations. Soil pH is depressed in many areas, particularly downstream of Bayard. Toxicity testing conducted for the BERA showed phytotoxicity to laboratory test species in areas with elevated copper and/or depressed pH. Multiple areas with pCu^{2+} levels below the PEL lack vegetative cover and if vegetation exists, it is dominated by one or two species (e.g., Lower Whitewater Creek stations U03-11254, U03-11255, U03-11256). Overbank areas, terraces and other areas where vegetation is more likely to become established are of most concern in the vegetation risk analysis. Such areas, like the side channel area of lower Whitewater Creek, and significant terrace areas farther downstream, have low pH and/or high copper concentrations. Whitewater Creek sampling locations included areas that lack living vegetation or are lacking typical herbaceous vegetation.

As noted in the BERA, an adequate reference area for the ephemeral drainage vegetation community was not identified, so quantitative impacts based on field measurements were not assessed. However, data from the BERA indicate that phytotoxicity test endpoints, and field measurements of species richness were correlated with pCu^{2+}. The disturbance and land-use history of the various vegetated bars and overbank areas was highly variable, as was the apparent vegetation community. Thus, impacts to the vegetation community from chemical impacts are likely for areas with pCu^{2+} values below the PEL. In addition, locations along Hanover Creek may be subject to vegetation risk from cadmium, zinc, and lead.

To extrapolate results from the Sitewide BERA to locations not included in the ERA analysis, the PEL and DEL levels based on pCu^{2+} were used. Figures 2.1-1 through 2.1-8 show locations with pCu^{2+} levels below the PEL ($pCu^{2+} < 7$) where the risk of vegetation impacts is greatest. A substantial proportion of the locations in Physical Reaches 3 and 6, as well as the Side Channel breakout area and the Lower Whitewater Creek areas were associated with soil pCu^{2+} below the PEL. In some of these areas, particularly the Side Channel area and Lower Whitewater Creek, the lack of vegetation cover suggests that wildlife habitat quality could be adversely affected. However, without a reference area and quantitative evaluation of habitat quality at other locations, the loss of wildlife habitat function cannot be quantified. A detailed discussion of the uncertainties in the terrestrial vegetation analysis is provided in the Sitewide BERA. The discussion included in that document is directly applicable to this analysis. However, it is expected that these uncertainties affect the conclusions to a small degree given the high level of predictive ability of the pCu^{2+} model and the correlations between pCu^{2+} and phytotoxic effects.

In terms of the predictive power of pCu^{2+} in estimating effects on vegetation, additional consideration of the pH in test soils was conducted after the completion of the Sitewide BERA.

In Figure 2.3-1 (Figure 2.5-1 from the Sitewide BERA), the laboratory test endpoints were plotted against the pCu^{2+} in the soil extracts used in ion-selective electrode measurements. Data are not available for pCu^{2+} in soil extracts from phytotoxicity test initiation and termination. So, pCu^{2+} was calculated based on copper and soil pH, using the pH measured by the phytotoxicity testing lab at test initiation and termination (Figures 2.3-2A and 2.3-2B). When these pCu^{2+} values are plotted against the test endpoints, results look somewhat different than when the extract data were used. When initiation pCu^{2+} values are used, the results could be interpreted as increasing the PEL from 5 to 6, based on the change in performance between tests at about 5.5 and 6. When termination pCu^{2+} values are used, they reveal a gap between pCu^{2+} 5 and 7 because pCu^{2+} results in this range either shift down to below five or up to seven. Selection of a PEL from these results is more difficult because of the gap in data between 5 and 7. However, they could indicate a higher PEL than previous estimates. The impact on the DEL is more apparent; the DEL could be shifted from 6-7 to 7-8. The PEL and DEL derived in the BERA were used in this assessment, but it may be necessary to determine if any community-level effects are present in areas with slightly higher pCu^{2+} than originally assumed.

Another important source of uncertainty is related to the use of non-native species in the laboratory toxicity tests. The regression slope and thresholds calculated using the laboratory phytotoxicity tests may change if native species were tested, but the degree and direction of change are unknown. At the time the studies were defined, investigators weighed the advantages and disadvantages of using native/acclimated plants versus standard test species, and the costs of doing both. Standard test species were used at the time of the investigation because their performance in laboratory tests, and responses to toxicants were well understood, and performance in tests using Site soils could be more definitively interpreted. Site plants are adapted to mineralized soils with elevated copper concentrations. However, copper concentrations in much of the H/WCIU corridor are elevated and pH depressed due to mining and mineral processing activities at the Site. Phytotoxic effects are apparent in the areas with highest concentrations and lowest pH, particularly in the downstream areas of Whitewater Creek. The levels of pCu^{2+} that were found to be associated with vegetation effects in the Sitewide BERA are clearly beyond those attributable to background copper concentrations or natural pH of the soil units present.

Finally, the effect of cattle grazing should also be considered in relation to community level effects on vegetation. No data showing the effect of cattle grazing in riparian areas with low pCu^{2+} versus ungrazed riparian areas with low pCu^{2+} are available. Qualitative observations within the Lower Whitewater Creek and Side Channel areas suggest that in the areas with low pCu^{2+} values there are visible differences in vegetation community structure and cover, but there is no apparent reason why grazing would be greater in those areas and would result in visible differences in vegetation. These qualitative observations support the effect of increased free copper on the vegetation community.

Additional community and/or laboratory phytotoxicity data from the H/WCIU could decrease the level of uncertainty in the extrapolation of results from the Sitewide BERA to the H/WCIU ERA. For example, additional data could be collected to verify the predictive ability of the pCu^{2+} model for community metrics at locations within the ephemeral drainages at the Site. In addition, updated soil pH measurements related to the effects of the white rain event could also be collected to determine current soil pCu^{2+}. However, before additional testing is undertaken, it is recommended that the potential impacts on Site risk management decisions be considered to ensure additional data are necessary.

3.0 RISK ANALYSIS FOR TERRESTRIAL WILDLIFE IN THE H/WCIU

This section provides additional risk analysis for terrestrial wildlife to supplement the analyses conducted as part of the Sitewide BERA (NewFields 2005). As noted previously, H/WCIU Phase 1 RI data (Golder 2000) on the nature and extent of contamination provide data in areas of the H/WCIU that were not available for the Sitewide BERA. In addition, vegetation and invertebrate tissue samples were collected at several RI soil sampling locations to provide better spatial coverage for the exposure analysis provided in the Sitewide BERA.

The Sitewide BERA concluded that potentially unacceptable risk was observed for the small ground-feeding bird receptor, primarily due to elevated copper concentrations in soil, vegetation and invertebrates. The BERA also indicated risks from several other COPCs to the small mammal receptor in the H/WCIU in areas upgradient of the former smelter location. Unacceptable risks to regional populations of wildlife were not predicted for any receptor, and localized populations of large and mobile receptors (e.g., ruminants and mammalian/avian predators) were predicted to be low.

For these reasons, the risk assessment in this document focuses on the small ground-feeding bird receptor and the small mammal receptor rather than the full suite of receptors that were evaluated in the BERA. Both of these receptors are important because they are significant food chain species as prey items for larger predators, and are good indicators for potential risk since they live in close contact with potentially contaminated soils and feed mainly on species that are potentially the most contaminated food items in the H/WCIU (i.e., terrestrial invertebrates and plants).

The ecotoxicologically-based SSLs generated in the Sitewide BERA were used as the primary tool for evaluating risks for the H/WCIU in the initial draft of this ERA (NewFields 2008). Since then, CMC completed additional sampling of terrestrial invertebrates and conducted Site-specific bioavailability testing on copper to supplement the available data and to evaluate the potential effects of the “white rain” event, moisture content, and bioavailability on exposure (Arcadis 2010). Based on a review of the additional data, NMED recalculated the benchmarks for the S/TSIU (NMED 2011). These recalculated benchmarks are also applicable for the H/WCIU. A detailed discussion of the recalculation of the copper benchmarks is provided in Section 3.3 and mirrors the recalculation done for the S/TSIU.

Data on metal concentrations in vegetation and invertebrates are also used to generate exposure analyses for areas not evaluated in the Sitewide BERA, including the Side Channel breakout area and Lower Whitewater Creek areas that were not sampled in the ERA field program.

3.1 Soil Exposure Point Concentrations

For comparison of soils concentrations to benchmarks, statistics to represent exposure point concentrations (EPCs) were calculated using two software packages. The 95th percentile EPC, as used in the Sitewide BERA, was calculated using Number Cruncher Statistical Systems (NCSS 2007), while a 95th upper confidence limit (UCL95) on the mean was calculated using ProUCL (USEPA 2011). Summary statistics were calculated using only data from the H/WCIU surface soils (<2000 µm), overbank sediments and channel bar sediments for the seven COPCs that were addressed in the detailed risk characterization portion of the Sitewide BERA. Table 3.1-1 presents statistics both for the entire IU and for each grouping of data by Physical Reach as discussed in Section 1.1.6.

3.2 H/WCIU Biota Tissue Sampling Results

Samples of vegetation, invertebrates, reptiles, birds, and small mammals were collected as part of the ERI and used in the Sitewide BERA to assess risks to wildlife. BERA samples were also collected from a small number of overbank areas and channel bars adjacent to Hanover Creek that were selected to be representative of these geomorphic features in the IU and were included in the modified gradient sampling and risk analysis, but were limited in spatial extent. To supplement the risk analysis for this H/WCIU ERA, vegetation and invertebrate tissue samples were collected from a subset of soil sampling locations in Hanover Creek (Physical Reach 1), Lower Whitewater Creek and in the Side Channel area.

The primary food items for the small ground-feeding bird and the small mammal receptors are assumed to be vegetation (both seeds and foliage) and terrestrial invertebrates. As a result, supplemental tissue sample collection was limited to those three tissue types. These samples were collected to augment the existing tissue database as well as to provide data from several areas within the IU that were not represented in the ERI data collection. Tissue data collected in 2007 are shown in Figures 3.2-1 through 3.2-7.

3.3 Copper Risk Analysis

The SSLs provided in the BERA were calculated for the No-Observed-Adverse-Effects Level (NOAEL) and Lowest-Observed-Adverse-Effects Level (LOAEL) TRVs based on Hazard Quotients (HQs) from 1 to 100, and bioavailability assumptions of 10 to 100 percent. The range of SSLs was calculated to provide risk managers with an evaluation of the effects of bioavailability and toxicity levels on potential risk management decisions (see Table 5.2-1 of the Sitewide BERA).

After completion of the Sitewide BERA, an alternative risk-based concentration (RBC) was calculated for the S/TSIU based on data provided by CMC regarding both the exposure model for the small ground-feeding bird and on the uptake of copper into terrestrial invertebrates and the relative bioavailability of copper from soils to the small ground-feeding bird receptor (CMC 2010).

The recalculated RBC is equal to 1,114 mg/kg. In addition, NMED provided CMC with a pre-FS Remedial Action Criterion (pre-FS RAC) for the S/TSIU for copper equal to 1,600 mg/kg. The pre-FS RAC value is included in the analysis below as an additional comparison point for the H/WCIU ERA.

The RBC and pre-FS RAC value were used along with copper concentrations in soils to calculate HQs associated with the H/WCIU data. The 95th percentile EPC for copper in the H/WCIU RI soil samples is equal to 1,300 mg/kg (Table 3.3-2). When compared to the RBC and S/TSIU pre-FS RAC, the corresponding HQs (Table 3.3-2) are 1.2 and 0.8, respectively.

The 95th UCL was not used as an EPC in the Sitewide BERA due to the non-random nature of sampling (NewFields 2005). However, data were collected using a more traditional approach for the H/WCIU Phase I RI which makes the 95th UCL an appropriate EPC for risk assessment purposes. The 95th UCL (calculated with ProUCL, USEPA 2011) equaled 743 mg/kg and resulted in HQs equal to 0.7 and 0.5 for the H/WCIU recalculated RBC, and the S/TSIU RAC, respectively. Table 3.3-1 presents the HQs based on comparisons to RBC and pre-FS RAC for each sampling location. Figures 3.3-1 through 3.3-9 show the relative distribution of copper concentrations in soil to risk based copper benchmarks calculated for the small ground-feeding birds at H/WCIU RI sampling locations (soil samples only).

The 95th percentile soil copper concentrations within the physical reaches or physical reach groupings had HQs greater than or equal to 1.0 using the RBC and pre-FS RAC in Physical Reach 3 (RBC only) and Physical Reach 4 (Table 3.3-2). Copper concentrations were highest at one location within Physical Reach 4 where copper was detected at 2,384 mg/kg and exceeded both benchmarks. However, available data within Physical Reach 4 were limited and insufficient to calculate a 95th UCL (Table 3.1-1).

The RBC and S/TSIU pre-FS RAC are expressed as copper concentrations in soils and can be used to assess risk based on soil data alone. However, data on copper concentrations (and other COPCs) in biota are available for a subset of locations. For these locations, intake of COPCs from food ingestion can be calculated for the receptors and compared to ingestion-based TRVs. HQs were calculated using the model presented in Appendix B. Because all of the invertebrate tissue data collected in H/WCIU were reported on a fresh weight basis, the fresh weight food ingestion rate (0.918 mg/kg BW/day) was used for the portion of the diet ingested as invertebrates. The dry weight ingestion rate was used for seed and soil exposure estimates.

Table 3.3-3a presents exposure and HQs calculated assuming a diet of 70% invertebrates and 30% seeds, while Table 3.3-3b presents exposure and HQs calculated assuming a diet of 100% invertebrates. Soil concentrations for the 2008 tissue sampling locations were calculated by taking the average copper concentration of the overbank samples (Golder 2008) in each area as the soil EPC. The HQs calculated using tissue data are shown in Figure 3.3-10. Soil copper concentrations in all of the locations presented in Tables 3.3-3a and 3.3-3b are less than both the pre-FS RAC and RBC.

As shown in Tables 3.3-3a and 3.3-3b, LOAEL HQs greater than or equal to 1.0 using Site-specific tissue data were calculated for copper at location B45.8-W in Physical Reach 1, ERA-28 in Physical Reach 3, SC-2 in the Side Channel, and LW-04A and LW-07A in Lower Whitewater Creek.

3.4 Additional COPCs

No unacceptable risks to any receptors from any COPCs other than copper were predicted in the Sitewide BERA. For that reason, no additional SSLs were reported in that document. Table 3.1-1 presents a comparison of the 95th percentile concentrations of each of the seven COPCs (upland soils only) discussed in the detailed risk analysis of the Sitewide BERA to the H/WCIU RI-specific soil samples.

Additional soil samples for the H/WCIU (Golder 2008) became available after the Sitewide BERA had been completed. For the expanded set of H/WCIU soil samples, the 95th percentile concentrations of cadmium, chromium, lead and zinc were all significantly higher than the 95th percentile concentrations evaluated as part of the Sitewide BERA. This indicates that the risk characterization in the Sitewide BERA may not be an adequate representation of risks for wildlife receptors inhabiting the riparian areas of the H/WCIU.

The H/WCIU 95th percentile soil concentrations of cadmium, chromium, lead, and zinc were compared to USEPA's Ecological Soil Screening Levels (EcoSSLs) (USEPA 2005) to determine if they exceed the conservative screening-levels made available since the completion of the BERA. The 95th percentile concentrations provided in Table 3.1-1 consistently exceed the lowest EcoSSLs for cadmium (0.36 mg/kg), lead (11 mg/kg) and zinc (46 mg/kg). These COPCs were carried forward in the H/WCIU ERA for further assessment.

Chromium concentrations shown in Table 3.1-1 were slightly higher than the avian EcoSSL (26 mg/kg) in Physical Reach 2 (26.1 mg/kg) and Physical Reach 3 (28.4 mg/kg) but never exceeded the mammalian EcoSSL (34 mg/kg). As shown in Table A-3, soil concentrations of chromium exceeded only the avian EcoSSL in one sample Physical Reach 2. The maximum detected concentration of chromium (U03-4314 = 32.4 mg/kg) resulted in an HQ equal to 1.2 based on the avian EcoSSL, and 0.9 based on the mammalian EcoSSL.

Given the low number and magnitude of exceedances of the conservative EcoSSL, chromium was not considered further as a wildlife COPC in the H/WCIU and risks from chromium are considered to be low.

Concentrations of molybdenum and selenium in H/WCIU soils, as a whole or in any physical reach, were not greater than those evaluated in the Sitewide BERA and, therefore, pose no unacceptable risk as concluded in the Sitewide BERA Report (NewFields 2005).

Risks to small ground-feeding birds and small mammals from exposure to cadmium, lead, and zinc are considered further in the following sections.

3.4.1 Cadmium

The 95th percentile concentration of cadmium within H/WCIU soils was equal to 5.93 mg/kg, higher than the 3.22 mg/kg calculated Sitewide in the BERA. The 95th percentile soil concentrations in Physical Reaches 1 (7.7 mg/kg), 2 (14.4 mg/kg) and 3 (4.62 mg/kg) all exceeded that 95th percentile for the Sitewide BERA. Exposure point concentrations within all other areas were less than calculated for the Sitewide BERA and, therefore, are predicted to be of similarly low risk for unacceptable effects to the wildlife inhabiting those areas.

Concentrations were highest within Physical Reaches 1 and 2 and are expected to be associated with historic lead/silver/zinc mines and mineral processing activities both upstream of and within those reaches (e.g., Groundhog Mine and Blackhawk Tailings, shown on Figure 1.0-1).

The relationships between cadmium concentrations in soils and concentrations in food items (foliage, seeds, and invertebrates) were evaluated and are presented in Appendix C. The exposure parameters, exposure estimation methodology, and toxicity reference values are provided in Appendix B. Some of the parameter values that were originally identified in the initial planning stages of the BERA have been changed based on new information becoming available since the beginning of the project, and use of Site-specific data to refine estimates.

The best-fit models for estimating cadmium concentrations in biota based on concentration in soils were identified for each forage/prey type. These models were then used to estimate exposure and risk to the small ground-feeding bird (Table 3.4-1) and the small mammal (Table 3.4-2) at soil sampling locations for which no biological tissue samples were available. HQs were calculated for individual locations to help identify areas of the Site contributing most to risk estimates for each of the physical reaches.

HQs less than 1.0 were calculated at all soil sampling locations and at 95th percentile soil concentrations for both receptors indicating that risk to wildlife inhabiting the H/WCIU from exposure to cadmium is low.

3.4.2 Lead

Upper bound soil lead concentrations within the H/WCIU (521.5 mg/kg) exceeded the 95th percentile soil concentration calculated in the Sitewide BERA (40.9 mg/kg) by more than a factor of 10 (Table 3.1-1). Concentrations were highest within Physical Reaches 1, 2, and 3 as well as in Bayard Canyon, and likely represent influence from upstream sources and/or from the former Groundhog Mine at which remedial activities have been conducted.

The 95th percentile concentrations within the three northernmost Physical Reaches were 840.7 mg/kg, 1,435 mg/kg and 389.5 mg/kg, respectively (Table 3.1-1). The lead concentrations in the three upland samples from Bayard Canyon were equal to 316 mg/kg, 551 mg/kg, and 1,836 mg/kg, respectively (Table 3.4-3).

As described for cadmium, the relationships between lead concentrations in soils and food items were evaluated (Appendix B) and the best-fit models for estimating concentrations in each food type were identified. These models were then used to estimate exposure and risk to both the small ground-feeding bird (Table 3.4-3) and the small mammal (Table 3.4-4) receptors at each soil sampling location within the H/WCIU. As discussed in the previous section, details of the exposure and risk calculations are provided in Appendix B.

For the small ground-feeding bird receptor, HQs calculated using the NOAEL TRV were greater than or equal to 1.0 at 12 soil sampling locations within the H/WCIU. HQs calculated using the LOAEL TRV were greater than 1.0 at three soil sampling locations: one location in Physical Reach 1 (U02-5003; HQ = 1.6), one location in Physical Reach 2 (ERA-32; HQ = 2.2), and one location in Bayard Canyon (U03-3004; HQ = 1.9).

The 95th percentile soil concentration in each of physical reaches was also used to estimate exposure and to calculate HQs for the small ground-feeding bird (Table 3.4-3). NOAEL HQs greater than 1.0 were calculated in Physical Reaches 1, 2, and 3; but only Physical Reach 2 had a LOAEL HQ greater than 1 (HQ = 1.5). An insufficient number of samples were available within Bayard Canyon to calculate a 95th percentile soil concentration.

No NOAEL HQs greater than 1.0 were calculated at any soil sampling location for the small mammal receptor.

3.4.3 Zinc

Concentrations of zinc in soils within the H/WCIU exceeded those observed and assessed in the Sitewide BERA (Table 3.1-1). The 95th percentile of soil zinc concentrations in all H/WCIU samples (2,448 mg/kg) was 25 times higher than the 95th percentile concentration calculated and assessed in the Sitewide BERA. Similar to lead, zinc concentrations are elevated within

Physical Reaches 1, 2 and 3 with 95th percentile concentrations equal to 3,148 mg/kg, 5,660 mg/kg and 1,498 mg/kg, respectively.

Best-fit models for estimating zinc concentrations in each food type were identified as described for cadmium and lead. These models were then used to estimate exposure and risk to both the small ground-feeding bird (Table 3.4-5) and the small mammal (Table 3.4-6) receptors at each soil sampling location within the H/WCIU. As discussed in the previous section, details of the exposure and risk calculations are provided in Appendix B.

For the small ground-feeding bird receptor, NOAEL HQs greater than 1.0 were calculated in every sample, but no sample had a LOAEL HQ greater than 1.0. Similarly, all NOAEL HQs calculated using the 95th percentiles were greater than 1.0, but corresponding LOAEL HQs were all less than 1.0.

For the small mammal receptor, NOAEL HQs greater than 1.0 were calculated at one location in Physical Reach 1 (U02-3100; HQ = 1.2) and one location in Physical Reach 2 (ERA-32; HQ = 1.9). No location had a LOAEL HQ greater than 1.0 and only the NOAEL HQ calculated using the 95th percentile in Physical Reach 2 was greater than 1.0 (HQ = 1.4).

3.4.4 Risk Calculations at Locations with Tissue Data Available

Cadmium, lead, and zinc risks were also estimated using the available tissue data and the same risk model as discussed in the previous section (Tables 3.4-7 and 3.4-8). For those locations lacking seed data (Lower Whitewater Creek and the Side Channel area), foliage tissue concentrations were substituted for seed tissue concentrations. For areas where paired soil and tissue samples were not available, the average soil concentrations from nearby sampling locations were used to represent the soil exposure portion of the HQ calculation. Drinking water was not included in the HQ calculations because it was an insignificant contributor to total exposure in the Sitewide BERA, and was not available in the immediate vicinity of most locations sampled in 2007. It is possible that some individuals could experience prolonged seasonal exposure to certain drinking water sources with high COPC concentrations. This is a potential source of uncertainty, as is it unclear where such exposure would occur.

For cadmium, no HQs greater than 1.0 were calculated for either receptor at locations where tissue data were available.

For lead, NOAEL HQs calculated for the small ground-feeding bird receptor were greater than 1.0 in Physical Reach 1 (5 locations), and LOAEL HQs calculated for the small ground-feeding bird receptor were greater than 1.0 in Physical Reach 2 and in Bayard Canyon (Table 3.4-1). For the small mammal receptor, all HQs calculated for lead were less than 1.0.

For zinc, at locations where tissue data were available, NOAEL HQs for the small ground-feeding bird receptor were calculated at all locations except LW-05-A in Lower Whitewater Creek. However, LOAEL HQs calculated for the small ground-feeding bird were greater than 1.0 only at location ERA-32 in Physical Reach 2. That location was also the only location where an HQ greater than 1.0 was calculated for the small mammal receptor (NOAEL HQ = 1.2); no LOAEL HQs exceeded 1.0 for the small mammal receptor.

3.5 Terrestrial Wildlife Conclusions

Soils in overbank areas and vegetated channel bars along the H/WCIU contain widely varying concentrations of metals. Concentrations of cadmium, copper, lead, and zinc exceed screening levels only in Physical Reaches 1, 2, 3, and 4.

For cadmium, no HQs greater than 1.0 were calculated for either receptor using tissue concentrations or soil concentrations, indicating that risk to wildlife inhabiting the H/WCIU from exposure to cadmium is low.

For lead, NOAEL HQs for the small ground-feeding bird receptor in Physical Reaches 1, 2, and 3 were greater than 1.0. The LOAEL HQ for Physical Reach 2 (1,435 mg/kg) was also greater than 1.0 (HQ = 1.5). LOAEL HQs calculated using soil data were also greater than 1.0 for the small ground-feeding bird receptor at one location in Physical Reach 1 (U02-5003 = 1.6) and at one location within Physical Reach 2 (ERA-32 = 2.2). At sampling locations where tissue data were available, only ERA-32 had a LOAEL HQ greater than 1.0 for the small ground-feeding bird (HQ = 2.6).

The soil lead concentration at U02-5003 was equal to 1,470 mg/kg and at ERA-32 was equal to 2,128 mg/kg. Based on these results the potential for unacceptable risk exists within Physical Reaches 1 and 2, particularly in soils with total lead concentrations exceeding 907 mg/kg based on the RBC calculated using the Bioaccumulation Factor (BAF) models presented in Appendix C to solve for a LOAEL HQ equal to 1.0.

For zinc, NOAEL HQs greater than 1.0 were calculated at every sampling location using both tissue concentrations and soil concentrations indicating that the NOAEL TRV may be too conservative to predict potential risk to the small ground-feeding bird receptor. A LOAEL HQ greater than 1.0 using tissue data was calculated at only one location (ERA-32) where soil zinc concentrations were equal to 8,349 mg/kg (LOAEL HQ = 1.7). Similarly, using soil concentrations to estimate tissue concentrations resulted in LOAEL HQs greater than 1.0 at only location ERA-32 (HQ = 1.5) and using the 95th percentile zinc concentration for Physical Reach 2 (HQ = 1.1).

Based on these results, the potential for unacceptable levels of risk to the small ground-feeding bird receptor appear to be highest in Physical Reach 2, particularly in association with areas where soil zinc concentrations exceed 4,800 mg/kg based on the RBC calculated using the BAF models presented in Appendix C to solve for a LOAEL HQ equal to 1.0.

For copper, the RBC and pre-FS RAC developed for the S/TSIU were the benchmarks used to assess risk to wildlife receptors. The RBC was exceeded at eight locations and the pre-FS RAC was exceeded at only one location.

Where tissue data were available for estimating exposure, and assuming a diet consisting of 70% invertebrates and 30% seeds, LOAEL HQs greater than or equal to 1.0 were calculated at (B45.8W) in Physical Reach 1, at ERI location ERA-28 in Physical Reach 3, and at LW-04A and LW-07A within Lower Whitewater Creek. In those cases, soil copper concentrations were less than the 1,114 mg/kg RBC.

Two locations (ERA-22 and ERA-28) had soil copper concentrations approximately equal to the 1,114 mg/kg RBC, and biota tissue data available for estimating exposures. A LOAEL HQ equal to 1.0 was calculated at ERA-28 and 0.8 for ERA-22. These results indicate that the RBC is a reasonable estimator of risk to the small ground-feeding bird and that sampling locations containing copper in excess of 1,114 mg/kg may be considered to pose unacceptable levels of risk to the small ground-feeding bird.

Because copper concentrations were generally higher in invertebrates than plants, a diet consisting of 100% invertebrates results in higher HQs. LOAEL HQs greater than 1.0 using the 100% invertebrate diet were calculated for locations with copper concentrations ranging from 192.3 mg/kg in the Side Channel area to 1,120 mg/kg in Physical Reach 3. While these results show uncertainty in the risk model, it is likely that the RBC is a reasonable indicator of risks to the small ground-feeding bird receptor. Tissue data were not available from any location with soil copper concentrations greater than the pre-FS RAC (1,600 mg/kg).

Areas of the H/WCIU that are found to have soil copper concentrations greater than the 1,114 mg/kg RBC should be considered as having an increased potential for risk of effects to small ground-feeding birds. Areas of the H/WCIU found to have copper concentrations in excess of 1,600 mg/kg should be considered to be the areas of highest risk to small ground-feeding bird populations and the birds inhabiting these areas may be exposed to copper levels that exceed the LOAEL dose, especially species that are resident to these areas and/or nest there.

No data on population size, nesting success or individual level effects are available for the Site to confirm whether adverse effects are occurring. Some adverse effects on some individuals seem likely, but the overall effect on the assessment endpoint is unclear.

4.0 RISK ANALYSIS FOR AQUATIC RECEPTORS IN THE H/WCIU

Overall, aquatic habitat at the Chino Mine Site is limited and is dominated by non-perennial drainages, stock tanks, and a few natural springs. The H/WCIU also has limited intermittent and perennial or long-term aquatic habitats. Surface water runoff in response to seasonal monsoon precipitation forms temporary pools along the drainages that provide habitat for a limited number of species adapted to such conditions. Therefore, the data collection and ecological risk analysis for H/WCIU focused on surface water and sediment conditions in these pools. The Sitewide BERA indicated that potentially unacceptable risks are present for aquatic biota in temporary pools along the Hanover and Whitewater Creek corridors. The COPCs of greatest concern were cadmium, copper, lead, and zinc.

4.1 Surface Water

The H/WCIU ERA surface water dataset is provided in Appendix A, Tables A-1 and A-2. Table 4.1-1 presents surface water data for cadmium, chromium, copper, lead, molybdenum, selenium and zinc compared to amphibian TRVs (Harfenist et al. 1989 and Schafer 1999a), Chiricahua leopard frog (*Lithobates = Rana chiricahuensis*) toxicity values (Little and Calfee 2008), and acute and chronic New Mexico Water Quality Criteria (NMWQC) (20.6.4 NMAC), and acute criteria developed on an approach by the Arid West Water Quality Research Project (AWWQRP 2006). The following describe the sources and context for the screening levels used in Table 4.1-1.

As is the case through much of the Chino Mine Site, aquatic components of the ecosystem in the H/WCIU are limited to ephemeral, intermittent and generally non-perennial streams. Ephemeral streambeds are above the regional water table and typically only flow in direct response to runoff events from precipitation. Flow in intermittent stream segments is more extended at certain times of the year, such as when the stream receives seasonal flow from localized groundwater flows and runoff events. At different times of year, both of these conditions exist in various parts of Hanover Creek, Whitewater Creek, and Bayard Canyon. Aquatic habitat in the H/WCIU is predominantly composed of temporary pools and non-perennial sections of Hanover Creek, Bayard Canyon, Lucky Bill Canyon, Whitewater Creek, and the Side Channel area of Whitewater Creek south of the tailings impoundments. Temporary pools along these reaches can persist for several weeks or longer (Golder 2007). Several stock ponds are also present in Lower Whitewater Creek and represent a more permanent source of water and aquatic habitat than the drainages.

For regulatory purposes, both the chronic and acute NMWQCs apply to surface waters classified as perennial or intermittent with a designated, existing or attainable use of “aquatic life” (i.e., permanent aquatic habitat). In cases typical of the southwestern part of the state with ephemeral water bodies where the designated use is defined as “limited aquatic life,” only the acute NMWQCs may be applicable for purposes of compliance with state water quality standards. However, no formal hydrologic classification according to NMED’s Hydrology Protocol in the H/WCIU drainages has been conducted. For risk assessment purposes, comparisons to both acute and chronic criteria are used as screening values. All sample locations are shown in comparison to the NMWQCs on Figures 4.1-1 through 4.1-3.

The NMWQCs were developed from federal nationwide AWQCs which are based on toxicity data from a wide range of freshwater taxa. Some of the taxa used in the nationwide AWQC are almost certainly not present in permanent or non-perennial aquatic environments at the Chino Mine Site. If the taxa that are present at the Site are more tolerant of exposure to the metal COPCs evaluated for the H/WCIU ERA, then using the NMWQC as a benchmark may overestimate risk. USEPA (1994, 2013) provides guidelines for recalculating the water quality criteria for the assemblage of species that are present at a given site.

The AWWQRP used this approach to recalculate criteria for cadmium, copper and zinc in effluent-dominated streams based on species that are more likely to be present in streams of the desert southwestern United States. The investigators examined the database of current species used to derive the ambient water quality criteria for a series of metals. The taxa included in the recalculation process were fish and invertebrates that are more representative of various waterbodies in the study areas. Databases were also augmented with new data not previously included in the AWQC documents. The revised databases were then used to derive acute and chronic water quality criteria according to the methods of Stephen et al. (1985).

For the purposes of the ecological risk assessment, revised acute criteria were recalculated for the H/WCIU for cadmium, copper, and zinc. This recalculation was conducted only for the H/WCIU ERA, and the recalculated benchmarks do not represent changes to state water quality standards. Results of the recalculation are shown in Appendix D. Copper criteria based on southwestern stream taxa could be substantially greater than the criterion calculated based on the national database, resulting in a less restrictive criterion. Recalculated cadmium and zinc criteria were also higher, but by lower amounts relative to existing AWQCs. The potential effects of alternative criteria for copper and zinc on interpretation of potential toxicity are discussed under the applicable sections below.

Additional water quality-based TRVs were included for amphibians, because their life cycle and potential sensitivity may differ from invertebrates and fish that are typically the basis for the NMWQCs. Amphibians potentially present are mostly limited to species that require water only for breeding and are either terrestrial as adults or can burrow into the mud as breeding pools begin to dry. Species potentially present in the project vicinity include the red-spotted toad, Great Plains toad, southwestern toad, Woodhouse’s toad, Couch’s spadefoot toad, New Mexico spadefoot toad, and plains spadefoot toad (Williamson et al. 1994). The tiger salamander and canyon treefrog are also potentially present.

The Chiricahua leopard frog (CLF) (*Lithobates = Rana chiricahuensis*) is listed as a federal threatened species by the U.S Fish and Wildlife Service (USFWS) (67 FR 40790). The 2007 USFWS recovery plan cites small populations present in some areas of Chino Mine property including Brown Spring, in Bolton Canyon, Ash Spring, Apache Tank, “and perhaps in Lucky Bill Canyon”. Lucky Bill Canyon drains directly to Bayard Canyon, but is primarily upstream of most recent mining areas in the H/WCIU. Populations on other parts of the Chino Mine property including West Lampbright, Main Rustler, West Rustler, and Martin canyons are likely extinct due to chytridiomycosis (USFWS 2007). Therefore, the presence of CLF in the H/WCIU is not known. Screening of water and sediment concentrations for toxicity to CLF is included in the analysis below, but is only relevant if the presence of the CLF is confirmed and NMED or other regulatory agencies need information to manage risk to this listed species.

General TRVs for amphibians are available from Harfenist et al. 1989. In addition, the U.S. Geological Survey (USGS) (under contract to the USFWS) completed a study of the effects of copper and several other contaminants on larvae of the Chiricahua leopard frog (Little and Calfee 2008).

No-observed-effect concentrations (NOECs) and lowest-observed-effect concentrations (LOECs) were available from Little and Calfee (2008) for cadmium, copper, and zinc (Table 4.1-2). The benchmarks used for comparison to surface water data in Table 4.1-1 represent the geometric mean NOEC and LOEC from the growth, development, and survival endpoints provided in Little and Calfee (2008), adjusted for Site-specific water hardness. The values were adjusted for hardness using the same assumptions that are specified for adjustment of NMWQCs for these metals (20.6.4.900.I NMAC).

4.1.1 Cadmium

Dissolved cadmium was detected in 24 of 29 total samples. The amphibian no-effect TRV (0.004 milligrams per liter [mg/L]) was exceeded in 13 samples. The recalculated acute criterion was exceeded at two locations: B-Ranch (2006 sample) and U03-9600 (1999 sample)(Table 4.1-1). The chronic NMWQC was exceeded in 18 samples. The two highest non-qualified results were detected at B-Ranch and U03-9600 (0.034 and 0.037 mg/L, respectively). These locations also had the highest concentrations of dissolved copper and zinc.

The Chiricahua leopard frog study (Little and Calfee 2008) showed no lethal effects at the highest dose, but weight gain and developmental endpoints were affected at 0.11 mg/L (LOEC). No effects were noted for any endpoint at 0.019 mg/kg (NOEC) for dissolved cadmium. The geometric mean NOEC and LOEC were equal to 0.039 and 0.11 mg/L respectively (at 102.9 mg/L hardness). Neither the geometric mean NOEC nor LOEC (converted using site-specific hardness) were exceeded in any of the summer rainfall pool samples.

4.1.2 Chromium

Chromium was detected in two samples, U03-9900 and B-Ranch, and the amphibian no-effect TRV (0.003 mg/L) was exceeded at sampling location U03-9900. No NMWQC were exceeded at either location. Detection limits exceeded the amphibian TRV at several locations. No CLF-specific benchmarks were available for chromium.

4.1.3 Copper

Dissolved copper was detected in all summer rainfall pool samples. Upstream of the Lucky Bill/Bayard Canyon confluence, copper concentrations in WWC-38.1 exceeded the recalculated acute screening level, the chronic NMWQC, the amphibian no-effect TRV (0.02 mg/L); dissolved copper concentration in sample U03-9000 exceeded the chronic NMWQC. Concentrations at all locations except LWWR-Ranchers Pond downstream of the Lucky Bill/Bayard Canyon confluence exceeded the recalculated acute screening level. The two highest copper concentrations were detected at locations Grunerud-1 (1.22 mg/L) and B-Ranch (2.34 mg/L) in Whitewater Creek upstream of Hurley, which also had the two lowest recorded pH values (4.6 and 4.2 SU, respectively).

The general amphibian TRV was exceeded at all locations downstream of the Lucky Bill/Bayard Canyon confluence. The general TRV represents a no-effect level for successful metamorphosis in frogs (Porter and Hakanson 1976, as cited in Harfenist et al. 1989). Fort and Stover (1997, as cited in Pauli et al. 2000) observed abnormal limb development in frogs at copper concentrations above 0.5 mg/L. Dissolved copper was detected above 0.5 mg/L in five summer rainfall pool samples at two locations from the Phase I RI sampling event (U03-9302 and U03-9600) and at three locations from the Golder (2007) sampling event (B-Ranch, Grunerud-1, and LWWC-1). The NOEC identified in Little and Calfee (2008) for growth endpoints for the Chiricahua leopard frog was equal to 0.003 mg/L. Reduction in body weights of the frog with chronic exposure to copper at 0.007 mg/L resulted in significantly reduced body weights when compared to the control. Length and Gosner stage endpoints were reduced at 0.047 mg/L with no effect observed at 0.007 mg/L. One hundred percent (100%) mortality (i.e., LC100) was observed in tadpoles within 2 weeks of exposure to 0.165 mg/L copper. The geometric means of the reported NOEC and LOEC endpoints were equal to 0.009 and 0.041 mg/L respectively (at 102.9 mg/L hardness). For screening the H/WCIU rainfall pool data, the geometric means were recalculated to adjust for hardness using the parameters established by NMED for calculating hardness-dependent copper criteria. Copper concentrations in two samples on Hanover Creek and Whitewater Creek upstream of Bayard Canyon (WWS-38.1 and U03-9000) exceeded the hardness-adjusted NOEC screening level. All locations in and downstream of Bayard Canyon except U03-9500 exceeded the NOEC; LOEC was exceeded at 12 locations; and the LC100 was exceeded at five locations.

4.1.4 Lead

Dissolved lead was detected in 15 of 29 total samples. The chronic NMWQC was exceeded in one sample collected during the Phase I RI sampling event (U03-9001). Neither the acute NMWQC nor the amphibian NOEC was exceeded in any sample. No Chiricahua leopard frog screening levels were available.

4.1.5 Selenium

Total selenium was detected in 18 of 29 samples. No detected total selenium concentrations exceeded the acute or chronic NMWQCs, or the amphibian no-effect TRV. No Chiricahua leopard frog screening levels were available.

4.1.6 Zinc

Dissolved zinc was detected in 23 of 29 total samples. Results exceeded the amphibian no-effect TRV (0.2 mg/L) at 16 sampling locations, the chronic NMWQC at 15 locations, and the acute AWWQRP at 14 locations. Similar to dissolved copper results, dissolved zinc concentrations were highest at B-Ranch and Grunerud-1 (7.89 and 5.84 mg/L, respectively).

The Chiricahua leopard frog study showed no adverse effects to growth, development, or mortality in and of the zinc concentrations tested. The hardness-adjusted NOEC and was exceeded at 16 locations. A Chiricahua leopard frog LOEC was not available.

4.2 Sediment

The H/WCIU sediment dataset is provided in Appendix A, Table A-3. Table 4.2-1 presents sediment data for cadmium, chromium, copper, lead, molybdenum, selenium, and zinc compared to sediment TRVs. Cadmium, copper, lead, and zinc were selected for further analysis in the H/WCIU based on results of the Sitewide BERA that indicated they were the primary aquatic COPCs of concern at the Chino Mine Site. Chromium, molybdenum, and selenium were included based on their presence as soil COPCs at the Site. Figures 4.2-1 through 4.2-9 show the sediment data with comparisons to the sediment TRVs.

Two types of sediment TRVs were evaluated. The probable effects concentration (PEC; MacDonald et al. 2000) represents a concentration above which significant effects are predicted. The PEC is generally analogous to the LOAEL TRV used for the wildlife endpoint. In addition, sediment toxicity thresholds (STTs) from the Tri-States Mining District (TSMD) were also considered for this assessment at the request of CMC due to their derivation from areas with historic mining impacts. The STTs were published in 2009 (MacDonald et al. 2009) and were not available for the draft H/WCIU ERA. Two SSTs are shown in Table 4.2-1; the SST_{10}

which is representative of a 10% reduction in survival or biomass, and the SST_{20} representative of a 20% reduction in survival or biomass of the test species. Similar to the water quality TRVs, PECs and STTs were developed based primarily on aquatic stages of insects that inhabit permanent water bodies. The ephemeral stream and temporary pond conditions at the Site can affect the assemblages of species that inhabit aquatic habitats. However, many of the PEC and STT values are based, at least in part, on toxicity tests of larval *Chironomus* sp, a ubiquitous group of dipteran midges that can be tolerant of adverse physical and chemical conditions. Therefore, the PEC and STT values have applicability as a screening tool in assessing risk, but definitive characterization of toxicity would require site-specific toxicity tests. Exceedance of the PEC was noted for cadmium (11 of 112 samples), copper (96 of 112 samples), lead (51 of 112 samples), and zinc (46 of 112 samples).

Copper concentrations did not exceed the PEC in any of the seven active channel sediment samples collected after the tailings spill event from the East Train pipeline into Whitewater Creek (August 1999). Those samples are shown on Table 4.2-1 as Sample IDs; U03-1500B, U03-1600B, U03-1700B, U03-1702B, U03-1900B, U03-1901B, and U03-1902B.

Background sediment data from the 2004 sediment background investigations (Golder 2004) were also considered. The median background concentrations from Exposure Reach 1 (includes Physical Reach 1, 2 and 3) were equal to 137 mg/kg, 56 mg/kg, and 242 mg/kg for copper, lead, and zinc, respectively. All of those concentrations were less than their respective PECs.

The STTs from the TSMD were also exceeded in multiple locations for copper, lead, and zinc as shown in Table 4.2-1. The SST_{10} for copper was exceeded at all locations (n=112) and at 43 and 7 locations for lead and zinc, respectively. The SST_{20} for lead and zinc were exceeded at 22 and 4 locations, respectively.

MacDonald et al. (2001) and MacDonald et al. (2009) both recommend the use of comparisons of sediment concentrations of multiple COPCs in order to more accurately predict the potential for benthic risk from mixtures of COPCs. When comparing the PEC, MacDonald et al. (2001) recommends using a calculation of the mean PEC quotient (mean PEC-Q), which is the mean of the ratio of the COPC/PEC for each COPC. Mean PEC-Qs greater than 0.556 were shown to be good predictors of sediment toxicity. Gray shaded cells on Table 4.2-1 indicate calculated mean PEC-Qs greater than 0.556.

MacDonald et al. (2009) recommend the use of the sum of the $COPC/SST_{10}$ for cadmium, copper, lead, and zinc as a predictor of effects to benthic invertebrates when the sum SST is greater than 2.97. As indicated in Table 4.2-1, the sum SST is greater than 2.97 at all locations except two in lower Whitewater Creek and one in the Side Channel area.

4.3 Aquatic Life Conclusions

In most cases where surface water exists in the H/WCIU, copper concentrations exceeded acute and/or chronic water quality criteria, as well as amphibian and Chiricahua leopard frog-specific NOECs and LOECs. Although the majority of the aquatic habitat is limited by ephemeral conditions, rainfall pool areas that may remain for extended periods of time can be utilized by invertebrate and amphibian species. Within the ephemeral areas of the H/WCIU, acute criteria represent the most applicable criteria assessing compliance with water quality regulations. In areas of more permanent water, such as stock tanks and rancher's ponds that could support breeding sites for amphibians and aquatic invertebrates, chronic criteria and amphibian TRVs provide useful comparison tools.

Acute NMWQCs were exceeded in summer rainfall pools for cadmium, copper and zinc, indicating a potential risk to aquatic invertebrates or other aquatic life that may utilize the water when present. Risks to aquatic life from sediment exposure also appear to be significant within summer rainfall pools. Cadmium, copper, lead, and zinc concentrations exceeded sediment TRVs that are potentially predictive of adverse effects on sediment organisms, if water is present long enough for colonization by aquatic invertebrates. However, the quality of the habitat and the highly ephemeral nature of the drainages with each seasonal precipitation event must be taken into consideration in any risk management decisions. More permanent water bodies that are potentially affected include stock ponds along Whitewater Creek (e.g., LWWC Rancher's Pond and U03-9301). The amphibian TRV, the Chiricahua leopard frog NOEC and LOEC, and chronic criteria for copper were exceeded indicating potential risk to aquatic life at these locations. At several locations, the LC-100 value for the Chiricahua leopard frog was exceeded. While this TRV is specific to the Chiricahua leopard frog, it also may be indicative of the potential for effects to other amphibians.

Consideration of future conditions may also be important in assessing risk to aquatic receptors. For example, potential flow from Whitewater Creek has been diverted eastward into the Bolton Draw drainage via a large excavation. Currently, flow in Hanover and Whitewater Creeks is likely ephemeral for much of the length of the H/WCIU. However, if conditions change such that flow is increased, residual salts in sediments may be solubilized and made more available to aquatic life. Such conditions could result if waste water from domestic water treatment or industrial use is discharged to Whitewater Creek above the diversion. In addition, considerations of habitat and physical stressors, such as potentially low oxygen levels in summer rainfall pools, should be considered in risk management decisions. Data on such stressors is not currently available.

5.0 UNCERTAINTIES

Uncertainty is an inherent part of risk assessment. The Sitewide BERA Report (NewFields 2005) presented a comprehensive evaluation of the uncertainties specific to the Sitewide BERA including:

- Sampling uncertainty and data gaps (i.e., uncertainty about spatial distribution of contamination as a consequence of limitations in sampling a site).
- Uncertainty in the selection of COPCs.
- Uncertainty in the natural (seasonal and/or annual) variability in the species, populations, communities, and ecosystems in question, as well as uncertainty regarding individual sensitivity to COPCs.
- Uncertainty in risk characterization using laboratory-based toxicity values and the HQ approach.
- Uncertainty in models and parameters used to estimate risk potentials.
- Uncertainty in assessing background COPC concentrations that may relate to calculated risk potentials.

A thorough discussion of these uncertainties is provided in the Sitewide BERA and all apply to the risk assessment for the H/WCIU.

In general, the Sitewide BERA presented a conservative determination of COPCs and a less conservative risk characterization that provided ranges of potential risks for use in making risk management decisions. Site-wide COPCs were selected based on a conservative screening approach that minimized the potential for Type I error, or the potential for not selecting chemicals that are potential risk drivers as COPCs. This approach allows similar limitations of Type I error within the H/WCIU since the COPCs from the Sitewide BERA were carried into this risk assessment.

Risk-based conclusions were reached in the Sitewide BERA based on potential ranges of risk to the assessment endpoints. Similarly, this risk assessment used the conclusions reached in the Sitewide BERA to assess potential risks within the H/WCIU. Conditions in the H/WCIU were reviewed in terms of the conditions that were discussed as potential risk drivers in the Sitewide BERA. This approach assumes similar uncertainties in the H/WCIU assessment as those that were identified and discussed in the Sitewide BERA.

There are additional uncertainties related to each assessment endpoint that require further discussion.

For the vegetation community assessment endpoint, risk-based models using pCu^{2+} in soils to predict community-level effects are a significant source of uncertainty. Although the Sitewide BERA showed strong correlations between pCu^{2+} in surface soils and community-level vegetation effects such as canopy cover and species richness, models designed to approximate reality are inherently uncertain. While it is unclear whether the pCu^{2+} over- or under-estimates the potential for community-level effects on the Site vegetation, this source of uncertainty should be considered in risk management decisions for the Site.

Similarly, for the small ground-feeding bird, risks were assessed within the narrow band of riparian areas potentially affected by water flowing in Hanover and Whitewater Creeks and in areas where sediments were deposited following high-flow conditions. The model used for the assessment assumed that the receptors focus all of their activities, including all feeding, to this narrow corridor. The assessment endpoint for wildlife receptors is based on effects to populations of receptors. It is uncertain whether a viable population of small ground-feeding birds inhabits the areas associated with elevated COPC concentrations or whether local populations utilize the riparian areas more frequently than more upland areas. It is likely that receptor populations utilize both the riparian areas and the surrounding upland areas, but the proportion of habitat use within each of the areas is unknown.

Finally, for the aquatic receptors endpoint, very limited data regarding habitat quality and aquatic community presence and structure is available. While there are clearly concentrations of COPCs in surface water and sediment within the H/WCIU that could have deleterious effects to the aquatic community, the current presence or health of the community is not known. This uncertainty should also be considered by risk managers when determining a risk-based course of action for the H/WCIU.

6.0 CONCLUSIONS AND RECOMMENDATIONS

Recent events and new data required the reanalysis of risks in the H/WCIU subsequent to the completion of the 2008 draft ERA report (NewFields 2008). The ‘white rain’ event may have a long-term effect on the pH of soils throughout the Site, and additional data related to the terrestrial invertebrates used in the exposure model provided a better estimation of risk to receptors ingesting invertebrates. Both have been included in this revised assessment.

Wildlife habitat throughout Hanover and Whitewater Creeks downstream to Hurley is impacted by both physical and chemical stressors. Physical disturbance due to grazing, construction, tailings removal, and flooding seems to have affected extensive areas in active channel and bar areas, as well as overbank areas and terraces where much of the vegetation associated with the ephemeral drainage occurs. Vegetated areas on overbanks and bars that were the focus of the ERA analysis contained elevated concentrations of cadmium, copper, lead, and zinc that could result in toxicity to vegetation and exposure of wildlife receptors to concentrations that exceed LOAEL benchmarks. However, it is unclear to what extent toxicity has contributed to the decrease in wildlife habitat quality under baseline conditions.

Elevated concentrations and increased risk primarily from lead and zinc appear to be related to sources in the Hanover Creek reach extending from the confluence with Whitewater Creek upstream to the AOC boundary, and to the Groundhog Mine area, which affects upper Whitewater Creek and Bayard Canyon.

Copper is the primary source of risk in more downstream areas, particularly downstream of Bayard on Whitewater Creek and in the areas of Bolton Draw where Whitewater Creek has been diverted. Elevated copper concentrations and depressed pH are observed in soils and overbank sediments throughout Whitewater Creek, extending to the Lower Whitewater Creek segments that are south of the main Chino Mine Site and tailing pond areas.

Aquatic habitat in the H/WCIU is primarily limited due to lack of persistent water sources. However, metal concentrations and low pH in water and sediment result in potentially toxic conditions in pools and during seasonal flows, as evidenced by exceedance of acute NMWQC, exceedance of TRVs for the Chiricahua leopard frog, and exceedance of sediment PECs in some locations. Direct measurement of toxicity of water or sediment was not conducted, nor was quantitative characterization of aquatic communities in permanent or temporary water bodies. Sediment and water toxicity tests with appropriate test species could be conducted to reduce uncertainty, but it is unclear whether results would alter risk management decisions. Quantitative characterization of aquatic communities in temporary water bodies is likely to be associated with substantial variability due to habitat differences and is unlikely to be a useful tool in determining the extent of toxic effects on aquatic fauna.

TABLES

Table 1.1-1

Summary of Assessment Endpoints for Chino Mine Ecological Risk Assessment

(Originally presented in the Sitewide BERA [NewFields 2005])

H/WCIU ERA

Management Goal:

Prevent or remediate adverse direct or indirect effects on ecological communities or populations of ecological receptors from toxic exposure to chemicals in mine waste

Assessment Endpoint	Risk Hypotheses or Question	Measures
	Exposure Assessment	
1. Vegetation Community of Upland Sites	1. COC concentrations in soils or vegetation do not exceed reference	Distribution of metals in soils and vegetation from site and reference areas
	2. COC concentrations in site soils do not exceed screening level TRVs	Metal concentrations in soils, TRVs for vegetation
	3. Nutrient levels are sufficient to support normal vegetation growth	K, P, NO$_2$+NO$_3$ TOC, pH in soils of site and background
	4. What proportion of landscape unit with [metals] in soils exceeding TRV or site-specific risk-based criterion	Distribution of elevated metal concentrations in soils or sediments
	Effects Assessment	
	5. Existing vegetation community at site is not degraded with respect to reference	Vegetation community structure in site and background areas; results of range quality assessment; sites located along gradient of conditions if possible
	6. Are COC concentrations or altered physical conditions in soils inhibiting recruitment?	Vegetation community and phytotoxicity test results for germination, root elongation, seedling growth from gradient of soil conditions
	7. Dose-response relationship exists between toxicity and soil contamination	" "
	8. What proportion of landscape unit(s) with adverse effects?	Spatial distribution of areas exhibiting adverse effects; elevated concentrations
	9. Are habitats in landscape unit fractionated by physical disturbance or chemical contamination?	Mapped distribution of vegetation types, wildlife species that may be restricted to habitat types against metal concentrations

Table 1.1-1

Management Goal:

Prevent or remediate adverse direct or indirect effects on ecological communities or populations of ecological receptors from toxic exposure to chemicals in mine waste

Assessment Endpoint	Risk Hypotheses or Question	Measures
	Exposure Assessment	
2. Vegetation Community of Ephemeral Drainages	1. COC concentrations in soils/sediments or vegetation exceed reference	Distribution of metals in soils and vegetation from site and reference areas
	2. COC concentrations in site soils exceed screening level TRVs	Metal concentrations in soils, TRVs for vegetation
	3. Dose-response relationship exists between residues and soil contamination	Metal concentrations in soils and plant tissues from co-located sites along gradient of conditions
	4. Nutrient levels are sufficient to support normal vegetation growth	K, P, NO_2+NO_3 TOC, pH in soils of site and background
	5. What proportion of landscape unit has [metals] in soils exceeding TRV or site-specific risk-based criterion?	Distribution of elevated metal concentrations in soils or sediments
	Effects Assessment	
	6. Existing vegetation community at site is not degraded with respect to reference area	Qualitative comparison of species present to unaffected or less affected sites (reference condition may not be available)
	7. COC concentrations are not accumulating in plant tissues	Metal concentrations in soils and plant tissues from gradient of conditions
	8. Are COC concentrations or altered physical conditions in soils inhibiting recruitment?	Phytotoxicity test results for germination, root elongation, seedling growth from gradient of soil conditions
	9. Dose-response relationship exists between toxicity and soil contamination	" "
	10. What proportion of landscape unit(s) with adverse effects?	Distribution of areas exhibiting adverse effects; elevated concentrations
	11. Habitats in landscape unit fractionated by physical disturbance or chemical contamination?	Mapped distribution of vegetation types, wildlife species that may be restricted to habitat types against metal concentrations

Assessment Endpoint	Risk Hypotheses or Question	Measures
	Exposure Assessment	
3. Herbivorous, Insectivorous, and Omnivorous Birds	1. COC exposures do not exceed TRVs (estimate by habitat type [i.e., upland, ephemeral drainage] and location on site)	COC concentrations in soils, seeds, foliage, invertebrates; TRVs for small and large granivorous, omnivorous, and insectivorous birds; Intake calculations
	2. COC in exposure media do not exceed reference levels	COC concentrations in soils, seeds, foliage from site units and reference area
	3. What soil concentrations are associated with exposures that exceed TRVs?	Correlation between COC concentrations in soils and either (a) concentrations in forage or prey or (b) bioaccumulation factors
	Effects Assessment	
	4. Habitat quality is not degraded in potentially affected areas	Habitat quality (vegetation community structure) in site vs. reference
	5. What portion of landscape unit with [metals] in soils and vegetation exceed risk-based criterion?	Spatial distribution of elevated metal concentrations in sediments, soils, and vegetation in landscape unit(s)
	Exposure Assessment	
4. Raptors	1. COC exposures do not exceed TRVs (estimate by habitat type [i.e., upland, ephemeral drainage] and location on site)	COC concentrations in soils, invertebrates, small mammals TRVs for raptors; Intake calculations
	2. COC in exposure media do not exceed reference levels	COC concentrations in soils, prey
	3. What soil concentrations are associated with exposures that exceed TRVs?	Correlation between COC concentrations in soils and either (a) concentrations in forage or prey or (b) bioaccumulation factors
	Effects Assessment	
	4. Habitat quality is not degraded in potentially affected areas	Habitat quality (vegetation community structure) in site vs. reference
	5. What portion of landscape unit with [metals] in soils and vegetation exceed risk-based criterion?	Spatial distribution of elevated metal concentrations in sediments, soils, and vegetation in landscape unit(s)

Notes: Phytotoxicity tests performed as part of the site-wide BERA (NewFields 2005).

All pCu^{2+} values calculated using the following equation: $pCu^{2+} = -0.56+(1.32*pH)-(0.18*\ln[Cu_{tot}])$ except for ERA-22, ERA-23, ERA-26, ERA-27, ERA-28, ERA-29, ERA-31, ERA-32, ERA-33.

ERA-22, ERA-23, ERA-26, ERA-27, ERA-28, ERA-29, ERA-31, ERA-32, ERA-33 are measured values and are not calculated using the Ephemeral Drainage equation.

Grey shading indicates samples in LWW and SC collected as active channel sediments. All other samples (white) are from bar and overbank locations.

N/A - No toxicity test conducted on the sample.

X - Statistically significant effects noted.

O - No statistically significant effects noted.

* Location ERA32 was remediated as part of the Groundhog Removal Action (Golder 2009).

1 Alliance According to *Comprehensive Vegetation Survey of The Chino Mine, Grant County, New Mexico (DBS&A 2000)*

Fluv For = Fluvial Forest and Shrubland

Mine Fac = Mine Facilities/Urban

2 Basal Cover refers to condition at ground surface

3 Canopy cover refers to vegetaion cover at 1 meter or less in height

4 Alien refers to non-native species (woody and herbaceous)

N/A: Not analyzed
NA: Not applicable
Note: *Italicized*: Concentrations found in foliage were used as seed tissue concentrations.
Calculation details are provided in Appendix A.
*Data from sampling location ERA-32 (Physical Reach 2) were replaced by the 95% UCL of post-removal composite samples (Golder 2009)

Table 3.4-1
Hazard Quotient Calculations at Locations Lacking Tissue Data
Cadmium; Small Ground-Feeding Bird

Notes:

Calculation details are provided in Appendix A.

Tissue concentration models are provided in Appendix B.

*Data from sampling location ERA-32 (Physical Reach 2) were replaced by the 95% UCL of post-removal composite samples (Golder 2009)

Table 3.4-2
Hazard Quotient Calculations at Locations Lacking Tissue Data
Cadmium; Small Mammal
H/WCIU ERA

Analyte	Location	Ingestion Rate Food (WW kg/kg BW/day)	Ingestion Rate Food (DW kg/kg BW/day)	Diet Composition			Tissue Concentration (mg/kg)			Food Exposure (mg/kg/day)				Percent of Diet as Soil	Ingestion Rate Soil (DW kg/kg BW/day)	Soil Concentration (mg/kg)	Bioavailability Factor	Soil Exposure	Total Dose	Toxicity Reference Value		Hazard Quotient	
				Foliage (0%)	Seed (30%)	Invertebrate (70%)	Foliage	Seed	Invertebrate	Foliage	Seed	Invertebrate	Total							NOAEL	LOAEL	NOAEL	LOAEL

Notes:

Calculation details are provided in Appendix A.

Tissue concentration models are provided in Appendix B.

*Data from sampling location ERA-32 (Physical Reach 2) were replaced by the 95% UCL of post-removal composite samples (Golder 2009)

Notes:

Calculation details are provided in Appendix A.

Tissue concentration models are provided in Appendix B.

*Data from sampling location ERA-32 (Physical Reach 2) were replaced by the 95% UCL of post-removal composite samples (Golder 2009)

Table 3.4-6
Hazard Quotient Calculations at Locations Lacking Tissue Data
Zinc; Small Mammal
H/WCIU ERA

Analyte	Location	Ingestion Rate Food (WW kg/kg BW/day)	Ingestion Rate Food (DW kg/kg BW/day)	Diet Composition			Tissue Concentration (mg/kg)			Food Exposure (mg/kg/day)				Percent of Diet as Soil	Ingestion Rate Soil (DW kg/kg BW/day)	Soil Concentration (mg/kg)	Bioavailability Factor	Soil Exposure	Total Dose	Toxicity Reference Value		Hazard Quotient	
				Foliage (0%)	Seed (30%)	Invertebrate (70%)	Foliage	Seed	Invertebrate	Foliage	Seed	Invertebrate	Total							NOAEL	LOAEL	NOAEL	LOAEL

Notes:
N/A: Not analyzed
Italicized: Concentrations found in foliage were used as seed tissue concentration
Invertebrate exposure calculated using fresh weight ingestion rate because invertebrate tissue data were reported in fresh weight in the BERA.
Seed and soil exposure calculated using dry weight ingestion rate since data were reported in dry weight in the BE
HQs greater than 1.
*Data from sampling location ERA-32 (Physical Reach 2) were replaced by the 95% UCL of post-removal composite samples (Golder 20

Table 3.4-8
Hazard Quotient Calculations at Locations With Tissue Data
Small Mammal

N/A: No comparable benchmark available.

N/D: Result non-detected

(1) No-Effect Concentration based on data presented in Harfenist et al. 1989 or derived in TM-1 (Schafer and Associates 1999).

(1a) Hardness adjusted geometric meanof no-effect concentrations observed in the Chirichaua leopard frog (Little and Calfee 2008).

(1b) Hardness adjusted geometric mean of lowest effect concentrations observed in the Chirichaua leopard frog (Little and Calfee 2008).

(1c) Concentration at which 100% mortality observed in the endangered Chirichaua leopard frog (Little and Calfee 2008).

(2) Hardness-based screening level calculated based on approach outlined in Arid West Water Quality Reserch Project. See Appendix D.

(3) Hardness based standard calculated with equation 1b or 2a of 20.6.4.900(I) NMAC; As Amended thorugh July 17, 2005.

(4) Criterion from 20.6.4.900(I) NMAC; As Amended thorugh July 17, 2005.

Shaded Cells indicate concentration is greater than risk-based concentration.

Notes:

Sample results presented as mg/kg.

For STT T_{10} and T_{20}: **100** Value exceeds the T_{10} value, but is less than
100 Value exceeds the T_{20} value. Note that no T_{20} value is available for copper.

For PEC-Q: **100** Value exceeds critical level for the Mean PEC-Q (0.556).
For $STT_{Cd,Cu,Pb,}$ **100** Value exceeds critical level for the Sum $STT_{Cd,Cu,Pb,Zn}$ (2.97).

Note: Results include those collected in the Post-Tailing Spill Sampling Event, November, 1999 (Golder 2000).

N/A: No comparable benchmark available.

Qualifiers: U: Result less than MDL. J: Value detected below detection limit.

T_{10}, T_{20}: Concentrations corresponding to 10% and 20%, repectively, reduction in survival or biomass from controls. (MacDonald et al., 2009).

PEC: Probable Effects Concentration.

Mean PEC-Q and Sum $STT_{Cd,Cu,Pb,Zn}$ *calculated as described in MacDonald et al., 2009.*

APPENDIX B

WILDLIFE RISK CALCULATION DETAILS

Table B-1

Exposure Parameters

Hanover-Whitewater Ecological Risk Assessment

Small Ground-Feeding Bird		
Food Ingestion Rate (Calculated from Nagy (2001) for passerine birds assuming a 12 gram bird)		
Wet Weight	0.918	kg food/kg BW/day
Dry Weight	0.287	kg food/kg BW/day
Diet Composition		
Foliage	0%	
Seed	30%	
Invertebrate	70%	
Small Mammal		
Food Ingestion Rate (Calculated from Nagy (2001) for Deer Mouse)		
Wet Weight	0.665	kg food/kg BW/day
Dry Weight	0.212	kg food/kg BW/day
Diet Composition		
Foliage	11%	
Seed	43%	
Invertebrate	46%	

Table B-2

Risk Calculation Equations

Hanover-Whitewater Ecological Risk Assessment

Equation 1: $HQ = \mathrm{Intake}_{\mathrm{tota}l}/\mathrm{TRV}$

Where: HQ = Hazard Quotient

TRV = Toxicity Reference Value

$\mathrm{Intake}_{\mathrm{total}}$ = Amount of COPC ingested per day from all sources (mg COPC/kg BW/day)

Equation 2: $\mathrm{Intake}_{\mathrm{total}} = \mathrm{Intake}_{\mathrm{food}} + \mathrm{Intake}_{\mathrm{soil}} + \mathrm{Intake}_{\mathrm{water}}$

Where: $\mathrm{Intake}_{\mathrm{food}}$ = Amount of COPC ingested per day from food (mg COPC/kg BW/day)

$\mathrm{Intake}_{\mathrm{soil}}$ = Amount of COPC ingested per day from soil (mg COPC/kg BW/day)

$\mathrm{Intake}_{\mathrm{water}}$ = Amount of COPC ingested per day from water (assumed to be negligible)

Equation 3: $$\mathrm{Intake}_{\mathrm{food}} = \mathrm{AUF} * \sum_{\mathrm{i}=1}^{\mathrm{m}} (\mathrm{IR}_{\mathrm{f}} * \mathrm{P}_{\mathrm{i}}) * \mathrm{C}_{\mathrm{ij}} * \mathrm{AF}_{\mathrm{ij}}$$

Where: AUF = Area use factor (unitless)

m = total number of ingested prey types

IR_{f} = total ingestion rate of food (kg/kg BW/day)

Note: seed and invertebrate ingestion calculated using dry weight;
foliage ingestion calculated using fresh weight.

P_{i} = fraction of food as prey $\mathrm{type}_{\mathrm{i}}$

C_{ij} = concentration of $\mathrm{COPC}_{\mathrm{j}}$ in prey $\mathrm{type}_{\mathrm{i}}$ (mg/kg)

$\mathrm{AF}_{\mathrm{ij}}$ = bioavailability factor of $\mathrm{COPC}_{\mathrm{j}}$ in prey $\mathrm{type}_{\mathrm{i}}$ (AFif = 1)

Equation 4: $\mathrm{Intake}_{\mathrm{soil}} = \mathrm{AUF} \ * (\mathrm{IR}_{\mathrm{f}} * \mathrm{P}_{\mathrm{s}} * \mathrm{C}_{\mathrm{js}} * \mathrm{AF}_{\mathrm{js}})$

Where: IR_{f} = total dry weight ingestion rate of food (kg/kg BW/day)

P_{S} = fraction of total food as soil/sediment

C_{ij} = concentration of $\mathrm{COPC}_{\mathrm{j}}$ in soil/sediment (mg/kg)

$\mathrm{AF}_{\mathrm{ij}}$ = bioavailability factor of $\mathrm{COPC}_{\mathrm{j}}$ in soil/sediment
