Mr. John Rhoderick, Director
Water Protection Division
New Mexico Environment Department
P.O. Box 5469
Santa Fe, New Mexico 87502

Dear Mr. Rhoderick:

Re: Draft Feasibility Study (FS) for the Smelter Tailing Soils Investigation Unit – Chino AOC

Freeport-McMoRan Chino Mines Company (Chino) submits under separate cover the *Draft Feasibility Study (FS) for the Smelter Tailing Soil Investigation Unit (STSIU)* under the Chino Administrative Order on Consent (AOC). This *Draft FS* is submitted per Appendix A, Section 2.7.7. of the AOC to the New Mexico Environment Department (NMED). Per the AOC Definitions Section, Item 10:

> *"Feasibility Study (FS) shall mean a comprehensive, written review, screening, and evaluation of alternatives developed during the Remedial Investigation to define the objectives of the response action, and to develop appropriate and necessary Remedial Action plans to be implemented at each Investigation Unit."*

Prior to the development of this *Draft FS* and per Appendix A, Section 2.7, Chino provided a letter detailing the *Commencement of the FS and FS Schedule* on November 19, 2010, and submitted the *Final FS Proposal for the STSIU* on October 17, 2011 to NMED. Per the approved FS Proposal in support of developing the draft FS, Chino completed the following activities:

- Chino completed survey and soil sampling requirements in 2011.
- Chino performed a phytotoxicity and vegetation study in 2014, as discussed below, following data evaluation of the 2011 sampling results.
- Chino completed the STSIU Amendment Plot Study in 2013, and provided a 5 Year Monitoring Report as discussed below.
- Chino completed a 5-year study with annual sampling to evaluate the effect of the 2008 "white rain" event within the STSIU. The resulting report is discussed below.
- The process for Use Attainability Analysis (UAA) Hydrology Protocol for drainages in the STSIU was completed with the acceptance by the NM Water Quality Control Commission (WQCC) in 2015.
- Chino performed site-specific copper toxicity studies for the STSIU and successfully petitioned the WQCC to amend the Surface Water Quality Standards (20.6.4 NMAC) in 2015.
- Chino implemented a supplemental field study to identify suitable reference areas for vegetation community sites in terms of soil toxicity to plants from copper for the FS analysis in October 2018 (resulting report is discussed below).

- Additional interim remedial actions (IRA) within the STSIU were completed following the approval of the FS workplan. These include the Hurley Railroad IRA completed in 2012, the Razorback Ridge IRA completed in 2014, and the B-Ranch IRA completed in 2019.

Four of the *Draft STSIU FS* appendices bring forward previous studies to support remedy option discussions and the FS decision-making making process.

- The *Year 5 Monitoring Report for the STSIU Amendment Study Plots*, dated December 2017, is attached as Appendix A. NMED provided a response letter dated January 8, 2019, for this report in agreement with Chino to include in the FS in order to review in context of this attached submittal.
- The revised *Year 5 Report on pH Monitoring to Evaluate the Effect of the White Rain on the STSIU is attached as Appendix B*. The previous draft was submitted to NMED in April 2017. The revised report with attached response document addresses NMED comments received September 18, 2017. Chino deferred submitting the revised report with NMED approval dated March 19, 2018, until it could be provided with the draft FS.
- A *Phytotoxicity and Vegetation Community Study Workplan* was submitted March 6, 2014, and conditionally approved by NMED in a letter dated March 10, 2014. Following the field investigation performed by Chino with NMED support and lab analysis of samples as per the workplan, a draft *Phytotoxicity and Vegetation Community Study* report was provided for informal review to NMED in 2018. The finalized report under Appendix C is formally submitted to NMED as part of and in support of this draft FS, which incorporates edits and technical group discussions generated from the NMED informal review. A response document is provided with the study to facilitate NMED's review.
- In October 2018, a supplemental field study was performed by Chino with NMED support to identify suitable reference areas for vegetation community sites in terms of soil toxicity to plants from copper. The results of this field study titled *2018 Reference Area Evaluation Technical Memorandum* are provided as Attachment A in Appendix D under *Methods and Results for Upland and Drainage Bank Analysis.*

The *Draft FS* was submitted today in electronic form to Mr. David Mercer. Please contact Ms. Pam Pinson at (575) 912-5213 with any questions or comments concerning this draft feasibility study for the STSIU.

Sincerely,

Tyler R. Johnson

1. Introduction

The Feasibility Study (FS) was prepared for Freeport-McMoRan Chino Mines Company (Chino) to develop and evaluate potential remedial alternatives for the Smelter Tailing Soils Investigation Unit (STSIU) at the Chino Mine Investigation Area, Grant County, New Mexico (site). This FS has been developed in accordance with the requirements in the Administrative Order on Consent (AOC) following the Comprehensive Environmental Response, Compensation, and Liability Act (CERCLA) guidance. The AOC, effective December 24, 1994, distinguishes between historical mineral processing activities and current operations at Chino.

1.1 Background

The STSIU is one of the Investigation Units identified within the Investigation Area (IA) of the AOC. The IA includes all areas in which environmental media may have been affected by historical operations at mining and processing facilities. The STSIU is located approximately 12 miles southeast of Silver City, and includes historical smelting facilities, mineral processing facilities, tailing impoundments, and surrounding areas (Figure 1-1). The STSIU is located to the east of the town of Hurley, New Mexico which contained the Hurley Smelter, and has previously been defined as all areas containing and proximal to Chino's former copper smelter and ancillary facilities, including the tailings disposal facility (SRK, 2008a).

In accordance with the AOC Scope of Work, a Remedial Investigation (RI) for the STSIU was conducted to generate the data necessary to evaluate the potential effects to human health and the environment from historically affected media in the STSIU. Data has been collected in the STSIU starting in 1995 and continuing to present day to determine potential impacts to soil, sediment, and surface water from historical mineral processing activities. The human health risk assessment (HHRA) and ecological risk assessment (ERA) have shown that areas of the STSIU have elevated metals concentrations and depressed pH in soil and surface water, as described in Section 3.1.1 and 4.1.1. The FS Proposal for the STSIU presented activities necessary to evaluate remedial alternatives that comply with New Mexico Environment Department (NMED) Pre-FS remedial action criteria (RAC) (Arcadis 2011a).

NMED issued Pre-FS RAC for the STSIU (NMED, 2010, 2011) including:

Soil

- 27 mg/kg arsenic (0-1")
- 100,000 mg/kg iron in soil (0-1")
- 5,000 mg/kg copper (0-1")
- 1,600 mg/kg copper (0-6")
- Cupric ion activity (pCu^{2+}) (hereafter referred to as "pCu") $\geq$ 5 where copper > 327 mg/kg. Note: Chino interprets this to actually mean NMED selected the STSIU Pre-FS RAC cupric ion activity (pCu2+) < 5 where copper is > 327 mg/kg.

Surface Water

- Water quality criteria contained in New Mexico Administrative Code (NMAC) §20.6.4.

These Pre-FS RAC values were developed based on the evaluations conducted in the RI, HHRA, and ERA. The FS and Record of Decision (ROD) will be completed consistent with the National Contingency Plan (NCP). Pre-

FS RAC are consistent with the use of preliminary remediation goals (PRG) by EPA in the NCP; therefore, new information can be used to refine the Pre-FS RAC and selection of alternatives (§300.430(e)(2)(i) NCP). Final remediation goals will be determined in the ROD. Further details about the Pre-FS RAC are presented in Section 2.4.

1.2 Objectives

The primary objectives of this FS, as initially presented in the FS Proposal (Arcadis 2011a), are to identify potential remedial areas and remedial technologies to address contaminated soil, sediment, and surface water in the STSIU. To achieve this, remedial action objectives (RAOs) were developed to define the basis for remediation, including numerical Pre-FS RAC as discussed in the previous section. Remedial technologies described in this document were assessed using the CERCLA FS criteria (Section 4.3, USEPA, 1988) to determine their potential to meet the project RAOs.

As part of the FS Proposal, a comprehensive literature review was completed, and potential remedial technologies were identified for application at the STSIU (Arcadis 2011a). Remedial technology alternatives evaluated in this report are unchanged from the FS Proposal and analysed individually and in comparison with each other using the following criteria: overall protection of human and ecological receptors, compliance with applicable or relevant and appropriate requirements (ARARs); long-term effectiveness and permanence; reduction in toxicity, implementability; and cost. The FS process followed to conduct the evaluation of alternatives presented in the FS includes the following steps:

- Summarize RAOs and Pre-FS RAC that address the key risk drivers and potential routes of exposure;
- Identify areas where potential remedial action(s) may be necessary to address RAOs and Pre-FS RAC;
- Identify and screen potential remedial technologies;
- Develop remedial alternatives; and
- Evaluate the remedial alternatives considering the FS criteria.

The above steps will be used to guide the selection of the preferred remedial alternatives.

1.3 Summary of Related Current Activities

Between the start of the AOC process in April 1995 and July 2022, there have been a number of site characterization or remediation activities in or near the STSIU at Chino. These include the following:

- AOC Interim Removal Action Work Plan and Completion Report for Interim Remedial Action, Hurley Soils Investigation Unit, (Golder, 2006, 2008)
- Phase 1 Remedial Investigation Proposal, Hanover and Whitewater Creeks Investigation Unit (Golder, 1999a)
- Comprehensive Groundwater Characterization Study (CGCS) (Golder 1999b)
- Phase II Revised Remedial Investigation Report, Hurley Soils Investigation Unit (Golder, 2000a)
- Phase 1 Revised Remedial Investigation Report, Hanover/Whitewater Creek Investigation Unit (Golder, 2000b)
- Remedial Investigation Proposal, Smelter Tailings Soils Investigation Unit (SRK, 2004)

- Slag Pile Characterization (Golder 2007a)
- Remedial Investigation, Smelter Tailings Soils Investigation Unit (SRK, 2008a,b)
- Smelter Tailings Soils Investigation Unit Ecological Risk Assessment (NewFields, 2008)
- Smelter Tailings Soils Investigation Unit Human Health Risk Assessment (Gradient, 2008)
- Smelter/Tailing Soils Investigation Unit Interim Removal Action Completion Report (“Golf Course IRA” Arcadis 2009)
- STSIU Terrestrial Invertebrate Bioaccumulation and Bioavailability Study (Arcadis, 2010a)
- Groundwater Quality Pre-FS RAC for Drainage Sediments Study (Arcadis, 2011b)
- Chino Mines Tailing Pond 1 & 2 Construction Quality Assurance Report (Golder, 2013a)
- Tailing Pond B/C Construction Quality Assurance Report (Golder, 2013b)
- Supplemental Completion Report, Interim Removal Action, Smelter/Tailing Soils Investigation Unit (“Railroad IRA” Golder, 2013c).
- Development of Site-Specific Copper Criteria Interim Report (Arcadis 2013a,b).
- Construction Quality Assurance Report, Lake One Reclamation (EMC^2, 2014)
- Supplemental Completion Report, Razorback Ridge Area, Interim Remedial Action, Smelter/Tailing Soils Investigation Unit (Golder 2015)
- Year 5 Monitoring Report for STSIU Amendment Study Plots (Arcadis 2017) (Appendix A)
- Year 5 Report on pH Monitoring to Evaluate the Effect of the White Rain on STSIU (Arcadis 2023) (Appendix B)
- B-Ranch Interim Remedial Action Completion Report Smelter/Tailing Soils Investigation Unit (Arcadis 2020)
- Assessment Report for Apache Tejo Wash (Golder 2023)
- Phytotoxicity and Vegetation Community Study (Arcadis 2018, Appendix C)
- Reference Area Technical Memorandum (Arcadis 2022, Attachment A in Appendix D)

A brief overview of the above reports for 2011 and prior years was included in the approved FS Proposal (Arcadis, 2011a). Several of the above reports have been updated or are new since the submittal of the FS Proposal in 2011. These reports are summarized below including reports that followed the FS Proposal.

Interim Removal Action for STSIU - Golf Course and Railroad

The *Interim Removal Action (IRA) for the STSIU* (Arcadis, 2006, 2009) and *Supplemental IRA for the STSIU* (Golder, 2013c) addressed elevated copper in surface soil to the north and west of Hurley, New Mexico. A former golf course existed to the north of the Town of Hurley. The North and South Golf Course designation refers to this area; the division between the north and south is the access road to the Chino facility entrance in Hurley. Areas to the east and west of Highway 180 on the west side of the Golf Course were included (Arcadis 2009) as well as acres alongside the railroad (Golder 2013c)[1].

The objective of the IRA was to remove areas where soil copper concentrations were greater than 5,000 milligrams per kilogram (mg/kg) (lateral delineation). Chino applied the NMED-approved residential RAC for the HSIU as a conservative measure in 2008. STSIU Pre-FS RAC was defined by NMED in 2009. Within the area exceeding 5,000 mg/kg copper, the excavation was completed vertically until the soil did not exceed 2,700 mg/kg copper or bedrock was encountered and, as a result, the spatially weighted 95 percent upper confidence limit (UCL) copper concentration in the 0-6 inch depth interval is estimated to be 1,314 mg/kg. Therefore, while this remedy was implemented prior to NMED issuing final pre-FS RAC, the soil removal meets the bird pre-FS RAC of 1,600 mg/kg.

Freeport-McMoRan Reclamation Services (FMRS) performed the IRA excavation activities in partnership with Arcadis, who conducted the field engineering services, which took place from January 2008 to August 2008. A supplemental IRA excavation of the remaining 32 acres between the town of Hurley and the golf course sites was conducted from August 2012 to December 2012 by TIPE Construction with oversight by Golder. Excavation depths during the IRA activities averaged three inches bgs for the total removal area. Based on confirmation sampling and refinement of the removal areas, approximately 170 acres of the proposed 190 acres in 2008 and approximately 32 acres in 2012 were ultimately remediated for a total of 202 acres. Final excavation volumes were determined by contractor load counts. The total volume removed during these IRAs are estimated at 68,112 cubic yards (Arcadis, 2009) and 22,125 cubic yards (Golder, 2013c).

Following the completion of the IRAs in 2008 and 2012, five years of monitoring was completed for both sites to document the successful revegetation of the IRA footprint (Arcadis 2014, Golder, 2018). The results of the five-year monitoring effort demonstrated the successful development of an early-seral stage mixed grama herbaceous alliance across the Golf Course sites. The canopy cover levels exceed the reference area guidance for canopy cover, and the data indicated that native species colonized the site with minimal cover from non-native species. Further, the vegetation limited erosion and controlled dust.

Interim Removal Action for STSIU – Razorback Ridge and B-Ranch

An IRA was completed east of Lake One in areas adjacent to the Whitewater Creek Diversion Channel and James Canyon in 2013 and 2014 in an area referred to as Razorback Ridge (Golder 2015). The objective of this IRA was to remove soils in areas with copper concentrations higher than 5,000 mg/kg, delineated laterally, as per the STSIU pre-FS RAC. Within the areas with higher than or equal to 5,000 mg/kg, soils were removed vertically to a depth of 1 to 2 feet as this surface soil volume was utilized as borrow fill material for reclamation. The final excavation area for the Razorback Ridge Area (which includes the East Removal Borrow Area) addressed in 2013 and 2014 was 94 acres. An additional 29 acres within the IRA Area were remediated through operational construction excavation and borrow activities prior to 2002. Soils were excavated to a depth of approximately 12 inches down to 40 feet during excavation for borrow material, exceeding the target remediation depths. See next

---

[1] The Highway 180 right-of-way (ROW) extends 50 feet on either side of the roadway and is considered by the New Mexico Department of Transportation (NMDOT) to be under its management. Any impacted soils within the Highway ROW will be addressed by NMDOT as part of their planned expansion of Highway 180 from a 2-lane roadway to a 4-lane roadway for the entire corridor between Bayard and Deming (NMDOT 2021). Chino expects to coordinate with NMDOT prior to planned construction and anticipates proposing an option for disposal of copper contaminated soils in compliance with existing regulatory requirements.

bullet section below. In all areas of removal, the Pre-FS RAC for the STSIU of 5,000 mg/kg for copper was achieved (Golder 2015). Approximately 113,000 cubic yards of soil (73 acres) from Razorback Ridge and 34,000 cubic yards of soil (21 acres) from the East Removal Borrow Area were removed between 2013 and 2014 and used for borrow material, specific to the IRA requirements.

An additional IRA was completed in 2019 for the B-Ranch area located adjacent to the reclaimed Slag Pile, the Golf Course IRA sites, as well as the Town of Hurley. Approximately 16,000 cubic yards of soil (22 acres) from B-Ranch site were removed. In all areas of removal, the Pre-FS RAC for the STSIU of 5,000 mg/kg for copper was achieved (Arcadis 2020).

Lake One and Tailing Pond Reclamation – Borrow Fill

As part of the CCP reclamation activities, Chino removed borrow fill, including wind-blown tailings (WBT), from the east and west sides of the historic tailings dams in 2013 (Golder, 2013a, 2013b, and 2013d) and 2014 (EMC[2], 2014). The extent of the borrow removal of more than 520 acres of land included the Razorback Ridge Borrow Area (87 acres), the South James Canyon Borrow Area (90 acres), Borrow Area A (71 acres), Borrow Area B (41 acres), Borrow Area C (50 acres), and Borrow D (153 acres). There was an additional 574 acres of WBT utilized as grading fill material where only the surface one foot depth was borrowed for Tailings Pond 1, 4, and 6. Borrow Areas A, B, and C, as well as Razorback Ridge, were used for fill and cover material for Tailings Pond 1, 2, B, C, 4, 6E and 6W and for Lake One. The top 2 feet of surface areas on the Razorback Ridge Areas and South James Canyon Borrow Area were removed and used as grading fill (i.e., below the base of the cover) within Lake One. Once placed, the WBT fill material also received a minimum 3-foot thickness of cover material along with the rest of the Lake One reclamation area. These borrow areas are addressed under the CCP.

Site Specific Copper Criteria Study

Arcadis conducted a copper water effect ratio (WER) study for the STSIU surface waters in 2011. As described in the WER work plan (Arcadis, 2011c), the purpose of the WER study was to evaluate the site-specific toxicity of copper in STSIU surface waters and to determine whether the hardness-specific copper criteria accurately reflect site-specific copper bioavailability and toxicity. A total of 24 STSIU water samples were collected in the WER study, including 18 toxicity test samples and an additional 6 analytical chemistry samples.

Results from the WER study were described in the *Development of Site-Specific Copper Criteria Interim Report* submitted to NMED in March 2013 (Arcadis, 2013a). The primary objectives of this Criteria Adjustment Interim report were to report all data collected as well as any deviations from the work plan, evaluate all collected data with quality control criteria described in the WER guidance (USEPA 1994, 2001), and determine if the collected data are sufficient to develop copper site-specific criteria (SSC) that can be applied to STSIU surface waters. Broadly, this study demonstrated that hardness-adjusted copper criteria are overly protective for surface waters of STSIU drainages, and the methods listed in Section 20.6.4.10, part D of NMAC can be successfully applied to surface water in STSIU drainages. The Interim WER Report also established that the toxicity and chemistry data collected were acceptable for deriving WERs when these data are compared to USEPA (1994 and 2001) WER acceptability criteria. Preliminary WERs were calculated according to USEPA guidance (USEPA 1994, 2001) and presented in that report. A site-specific copper WER model was subsequently developed to derive adjusted copper criteria in STSIU surface waters in the *Revised Site-Specific Copper Toxicity Model Report* submitted to NMED in October 2013 (Arcadis, 2013b). The site-specific criteria for STSIU surface waters were adopted by NMED and are contained in NMAC §20.6.4.809.

STSIU Amendment Study Plots

Chino implemented the STSIU Amendment Study in 2008 based upon an NMED-approved work plan to explore the possible remedial options to determine if lime and organic matter amendments with or without tilling could be an effective and feasible remedial action to address the elevated copper concentrations and depressed pH in surface soils within the STSIU (Arcadis, 2008a). The study tested the longevity of pH stabilization, copper sequestration ability, vegetative re-colonization, and constructability (Arcadis 2017, see Appendix A).

In June of 2008, Chino applied lime and organic matter to three test plots, and one test plot was used as a control with no amendments or tilling. A control plot with no treatment was also established adjacent to each of these four plots. During the application of lime and organic matter, two of the test plots on relatively level ground were also tilled. Chino conducted monitoring of the copper, pH, and vegetation cover before and after amendment application. The results from the monitoring events were presented in the *Year 5 Monitoring Report for Smelter/Tailings Soils Investigation Unit Amendment Study Plots* (Arcadis 2017). In summary, an unexpected white rain (discussed in next section) increased pH and pCu significantly and reduced copper uptake to plants of all the plots, which was sustained over the 5-year monitoring period. As a result, the treatments added to the soil in the plots provided minimal if any additional benefit in further reducing copper impacts to the plant community because the white rain already significantly improved the soil chemistry. The white rain increased plant species richness but had a small effect on total plant cover. The vegetation community of the steeper plot was degraded by the two amendments, with a loss of rangeland grasses and desirable shrubs. The tilling and mixing of lime amendments into the soil tended to increase pH but degraded the plant community on the fair rangeland plot and improved the plant community on the poor rangeland plot; however, the recovery of degraded conditions could take decades. Liming and tilling are only recommended in relatively flat, poor rangeland rocky areas where phytotoxicity from copper can be demonstrated. Tilling alone has been shown to be effective and should be tried first at an 8-inch depth and deeper to evaluate the proper depth but only on slopes < 13% and where the rangeland condition is poor. Organic matter application was not recommended.

STSIU pH Monitoring

A significant shift in pH upward was observed in the STSIU following a “white rain” precipitation event on January 7, 2008 (Arcadis, 2008b). To quantify the permanence of this trend, Chino submitted, and NMED approved, the Soil pH Monitoring Work Plan in 2010 (Arcadis, 2010b). The Work Plan outlined eighteen locations (increased to 22 in 2011) to monitor soil pH over 5 years[2], with annual reports provided to NMED after each sampling event and a final, Year 5 report summarizing the results of the pH monitoring effort (Arcadis 2023, see Appendix B).

The results of the 5-year study showed that the 2008 white rain greatly benefitted the STSIU soils by increasing the pH and pCu of the acidic soils, making copper less bioavailable due to the increase in copper adsorption by secondary soil minerals, such as iron hydroxide, at higher pH values (Arcadis 2023). The increase in pCu led to a decrease in the uptake of copper into living organisms. The ultimate result appears to be reduced toxicity to wildlife and their food sources and improved wildlife and rangeland habitat. Based on Mining and Minerals Division (MMD) guidelines and mineralogical analysis, the potential of STSIU soils to generate acid is consistently low in most areas. Based on results reported in the *Year 5 Report on pH Monitoring to Evaluate the Effect of the White Rain on the Smelter/Tailings Soils Investigation Unit* (Arcadis 2023), persistence in the future cannot be predicted with certainty, and additional five-year monitoring is recommended as part of the STSIU FS to confirm

---

[2] Soil excavations from reclamation borrow activities over the monitoring period removed five of the sample locations, so five additional locations were added in 2012. Overall, 17 locations were monitored all five years.

the prediction that the pH increase should be sustained. Appendix B includes the revised report plus a brief response to NMED comments (see Appendix I of the report for all response to comments).

Phytotoxicity and Vegetation Community Study

The site-wide and STSIU-specific ERAs stated that elevated concentrations of copper and other metals, combined with depressed soil pH, have led to a risk of phytotoxicity for some areas of the Site based on site-specific greenhouse phytotoxicity studies and plant community surveys in 1999 (NewFields 2006, NewFields 2008, Schafer and Associates 1999a,b). For plants, these ERAs linked the toxic action of total copper in the shallow surface layer of the soil to cupric ion activity, quantified as pCu. Site conditions changed since the original studies, however, requiring additional studies; specifically, the two historical smelter stacks were shut down in 2002 and demolished in 2007. Reclamation of Lake One and older tailing dams was also completed. Additionally, a significant upward shift in soil pH was observed at STSIU following the “white rain” precipitation event on January 7, 2008. The change in soil pH due to the white rain event has lowered cupric ion activity of the soil (Arcadis 2023) and, more importantly, possibly changed the complex soil geochemistry (e.g., cation exchange capacity) in a manner that could shift the relationship between pCu and plant and community endpoints. In addition, the 1999 phytotoxicity and community studies did not explicitly account for site-specific seeds, representative background, or potentially confounding physical and chemical factors across various soil types.

New studies were proposed by Chino in 2013 to address these changes, approved by NMED in 2014. Data collection was completed in 2015, results submitted in April 2017 and re-submitted in August 2017 for NMED review. The report in Appendix C was updated in 2018 and addresses the last set of NMED comments provided in January 2018; the response to NMED comments are attached at the end of the report. The results generally support that the ranges of the probable effects level (PEL) and de minimis effects level (DEL) could be lower than the 1999 study. The native site species did not always perform better than non-native species, and their addition produced less of a change in the results relative to 1999 results. Dose-response models for each category of soil (bedrock, steep slope, flat granular, flat rocky) produced a different DEL or PEL. The variable DEL and PEL values, depending on soil conditions, create uncertainty around the application of a pre-FS RAC for vegetation across all soil types, and on whether more harm than good will result if simple cleanup criteria are used across the entire IU. This study’s information was useful for the FS because it defines areas on the site by the four soil categories of bedrock, steep slope > 13%, flat granular, and flat rocky soils that strongly influence plant responses to pCu. The community study was based on site soils that were not homogenized in the laboratory (maintaining pCu stratification) and are the most representative of field conditions.

Draft Technical Memorandum on pCu Reference Area Visit and Analysis

Based on NMED comments regarding the phytotoxicity report and an August 2018 meeting between Chino and NMED, Chino proposed sampling additional locations for “reference” or “background” to increase confidence in conclusions. Reference areas were identified in the field with NMED, and Chino sampled the community metric endpoints of cover, richness, and rangeland condition (via Observed Apparent Trend [OAT] score) as well as soil chemistry (pH, total copper, and sulfate) across all four soil categories identified in the phytotoxicity study (Arcadis 2018): flat granular, flat rocky, bedrock, and steeper slopes (>13%). Eight reference areas were sampled for soil and surveyed for three plant endpoints (OAT score, richness, cover) in October 2018, bringing the total reference area dataset to be used for comparing plant communities on site to reference areas off site to ten, given that two reference sites (wildlife reference north and STS-PT-2013-26) had been sampled previously. Three additional STSIU onsite locations were sampled or surveyed. Two of these were sampled for soil chemistry and/or plant community data to evaluate pCu at highly overgrazed areas on the site, and one (wildlife reference south plot) was sampled and surveyed along with the wildlife reference north location to calibrate changes[3] in plant cover due to the climatic differences over 3 different years of sampling (2011, 2014, 2018); this repeat survey ensured that on-site and off-site area data are comparable.

Like the two previously sampled reference locations, all new reference locations had sulfate concentrations and pH in the soil within the expected range for the geology and soils of the location, indicating that they do not have any smelter or windblown tailing impacts. These results support that the new reference locations adequately represent background conditions without mining impacts. The new reference area data are **not** incorporated in the phytotoxicity study report, however, because it has been through several review cycles with NMED. Instead, data from the new reference locations are evaluated in this FS as to how they affect DELs and PELs for pCu impacts on the vegetation community. DELs and PELs presented in the community section of the phytotoxicity report were recalculated with the new data. The recalculation is important because the phytotoxicity study did not have any reference areas representative of flat rocky, bedrock, or slopes > 13%. Previous community PEL and DEL were based on the flat granular reference area, underestimating the values for the other 3 soil categories. When averaged across all three endpoints, the DELs ranged from 5.83 to 8.08, and PELs ranged from 2.97 to 4.60, with the highest values in the flat rocky soil category. The Tech Memo (Arcadis 2022) is provided as Attachment A to Appendix D.

Assessment Report for Apache Tejo Wash

Chino documented completion of an NMED request for a “ground survey” of the entire Apache Tejo drainage system in 2021. The “ground survey” includes historical information, as well as reconnaissance results and property ownership information. The “ground survey” covers the entire wash from the Chino tailing impoundments to Whitewater Creek, including two tributaries to Apache Tejo Wash. Chino also characterized tailing and other materials along the wash and interpreted the data with respect to the potential for exposure and the potential for re-release to other media, including groundwater. The Assessment Report concluded that the potential for constituents to infiltrate to groundwater is low; the tailing in the channel and the Big Berm generally showed little to no potential to generate acid or leach metals (Golder 2023). The depth to groundwater is 100 feet along the wash, and the vadose zone is comprised of alluvium and Gila Conglomerate with neutralizing potential. Also, there is limited potential to re-release constituents to surface water because recent, cleaner sediment has covered much of the historical tailing along the wash with a couple limited exceptions. The data were screened against STSIU Pre-FS RAC for birds and vegetation and no further action was recommended. Apache Tejo Wash will be further considered under Discharge Plan DP-1340 Sitewide Abatement.

1.4 AOC Requirements

The AOC between Chino and NMED became effective on December 24, 1994 and requires Chino to conduct the following work:

- Assess present STSIU condition in the investigation area associated with risks to public health and welfare of the environment;
- To the extent necessary to select a remedy, or remedies, evaluate alternative remedial technologies appropriate for the IU in the investigation area; and

---

[3] Wildlife Reference North and South locations were sampled each year of community sampling to calibrate cover. The wildlife reference south location was originally thought to be a reference area but had lower pCu once sampled and became a “de minimis” location along with three bedrock reference locations that had lower pCu than 5 (see phytotoxicity report).

- Implement the selected remedy or remedies.

FS activities that were identified in the AOC Scope of Work and described in the FS Proposal (Arcadis 2011a) include, but are not limited to:

- Description of current situation;
- Treatability studies and identification and screening of potential applicable technologies;
- Development of remedial alternatives;
- Initial screening of remedial alternatives;
- Detailed evaluation of remedial alternatives;
- Description and justification of preferred alternative; and
- Production of the FS report.

This FS addresses the above bullets.

1.5 Organization of FS

This FS was prepared to determine and fulfil the needed data requirements of the AOC identified FS activities. The FS is organized as follows:

- Section 1.0: Introduction
- Section 2.0: Regulatory Components of the FS
- Section 3.0: Description of Current Situation: Soil
- Section 4.0: Description of Current Situation: Surface Water
- Section 5.0: Identification and Screening of Potential Applicable Technologies
- Section 6.0: Assembly and Development of Remedial Alternatives
- Section 7.0: Analysis of Alternatives
- Section 8.0: References

2. Regulatory Components of the FS

There are a number of regulatory components associated with an FS. Section 2.1 presents the specific FS tasks that are stated and required in the AOC associated with STSIU. Section 2.2 presents the ARARs associated with the STSIU. Sections 2.3 and 2.4 provide details on the RAOs and the Pre-FS RAC that have been developed for the STSIU. Finally, Section 2.5 describes the AOC STSIU study boundaries.

2.1 AOC FS Tasks

AOC FS Tasks were presented in the FS Proposal (Arcadis 2011a) and are updated herein based on additional work completed.:

Description of Current Situation

Updates to the current situation are detailed in Sections 3 and 4.

Treatability Studies and Identification and Screening of Potentially Applicable Technologies

Technologies were identified in the approved STSIU FS Proposal (Arcadis 2011a). There were no treatability studies identified but the Amendment Study is an example of an on-going treatability study that was started before the FS Proposal was submitted and approved. The technologies that were identified to carry forward are incorporated into remedial alternatives herein.

Development of Remedial Alternatives

Remedial alternatives were developed in the FS Proposal (Arcadis 2011a) and no updates were identified through the implementation of that proposal.

Initial Screening of Remedial Alternatives

The initial screening of remedial alternatives was completed in the FS Proposal (Arcadis 2011a) and no additional alternatives were identified for screening following the implementation of that proposal.

Evaluation of Remedial Alternatives

Remedial alternatives were evaluated in the FS Proposal (Arcadis 2011a) and no changes to that evaluation have been identified through the implementation of that Proposal. The remedial alternatives identified in the FS Proposal that were carried forward into the FS include the following:

Soil

- No Action
- Monitoring
- Excavation and Reuse
- Excavation and Disposal
- Limestone and Organic Matter Soil Amendment
- Tilling
- Ferrihydrite Soil Amendment
- Soil Cover

- Phytostabilization

Surface Water

- No Action
- Monitoring
- Excavation (In-Drainage, Upland, or Stock Ponds)
- In-Stream Removal of Suspended Sediments
- Limestone Treatment
- Sediment and Erosion Control

Description and Justification of Preferred Alternative

In the FS Report, Chino shall describe and justify its preferred alternative based on the criteria listed above.

2.2 Applicable or Relevant and Appropriate Requirements

Applicable or Relevant and Appropriate Requirements (ARARs) are those cleanup standards, standards of control, and other substantive environmental protection requirements, criteria, or limitations promulgated under federal or state law that specifically address the situation at a CERCLA site. The requirement is applicable if the jurisdictional prerequisites of the standard show a direct correspondence when objectively compared to conditions at the site. An applicable federal requirement is an ARAR. An applicable state requirement is an ARAR only if it is more stringent than the federal ARAR.

If the requirement is not legally applicable, then the requirement is evaluated to determine whether it is relevant and appropriate. Relevant and appropriate requirements are those cleanup standards, standards of control, and other substantive environmental protection requirements, criteria, or limitations promulgated under federal or state law that, while not applicable, address problems or situations similar to the circumstances of the proposed response action (relevant) and are well suited to the conditions (appropriate) of the site. A requirement must be determined to be both relevant and appropriate in order to be considered an ARAR.

The criteria for determining relevance and appropriateness are listed in the Code of Federal Regulations (40 CFR), Section 300.400(g)(2), and include general comparisons between the following:

- The purpose of the requirement and the purpose of the action;
- The medium regulated or affected by the requirement and the medium contaminated or affected at the site;
- The substances regulated by the requirement and the response action contemplated at the site;
- Any variances, waivers, or exemptions of the requirement and their availability for the circumstances at the site;
- The type of place regulated and the type of place affected by the release; and
- Any consideration of use or potential use of affected resources in the requirement and the use or potential use of the affected resources at the site.

According to the USEPA CERCLA guidance, a requirement may be “applicable” or “relevant and appropriate” but not both (USEPA, 1988). Identification of ARARs must be done on a site-specific basis and involves a two-part analysis: first, a determination of whether a given requirement is applicable; and then, if it is not applicable, a determination of whether it is, nevertheless, both relevant and appropriate. When the analysis determines that a requirement is not applicable but is both relevant and appropriate, the requirement must be compiled with the same degree as if it were applicable.

ARARs are generally divided into three categories: chemical specific; location specific; and action specific in accordance with USEPA guidance (USEPA, 1988):

- Chemical Specific: Chemical specific ARARs are generally health or risk based numerical values or methods applied to site-specific conditions that results in the establishment of a cleanup level. Many potential ARARs associated with particular response alternative (such as closure) can be characterized as action-specific but include numerical values or methods to establish them so they fit in two categories, chemical-specific and action-specific.
- Location Specific: Location specific ARARs are included for environmentally sensitive areas including riparian and other hydrologic resources, and biological and other natural resources are the resource categories relating to location-specific requirements potentially affected by the STSIU remedial actions.
- Action Specific: Action specific ARARs are included for the potential remedial actions that will be used in the STSIU.

This classification was developed to aid in the identification of ARARs. Some ARARs do not fall precisely into one group or another. ARARs are identified on a site-specific basis for remedial actions where CERCLA authority is the basis for cleanup.

For the determination of relevance and appropriateness, the pertinent criteria were examined to determine whether the requirements address problems or situations sufficiently similar to the circumstances of the release or response action contemplated, and whether the requirement is well suited to the site. A negative determination of relevance and appropriateness indicates that the requirement does not meet the pertinent criteria.

To qualify as a state ARAR under CERCLA, a state requirement must be:

- A state law or regulation;
- An environmental or facility law or regulation;
- Promulgated;
- Substantive;
- More stringent than federal requirements;
- Identified in a timely manner; and
- Consistently applied.

To constitute an ARAR, a requirement must be substantive. Therefore, in some cases only the substantive provisions of requirements identified as ARARs in this analysis are considered to be ARARs. Permits are considered to be procedural or administrative requirements though may contain substantive requirements that are ARARs which must be attained and/or qualify as “to be considered” (TBC) materials that may be used in determining the necessary level of cleanup for protection of human health or the environment.

Provisions of generally relevant federal and state statutes and regulations that were determined to be procedural or not environmental in nature, including permit requirements, are not considered ARARs. CERCLA Section 121(e)(1), (42 USC Section 9621(e)(1)), states that “No Federal, State, or local permit shall be required for the portion of any removal or remedial action conducted entirely on-site, where such remedial action is selected and carried out in compliance with this section.” Consistent with 40 CFR, the term “on-site” is defined for purposes of this ARARs discussion as “the areal extent of contamination and all suitable areas in very close proximity to the contamination necessary for implementations of the response action.

In addition to ARARs, non-promulgated advisories, proposed standards, criteria, guidance, or policy documents developed by the federal or state government, or other information referred to as TBC materials may also be used in conjunction with ARARs to achieve an acceptable level of risk at a site. Although not legally binding, TBCs may be used when determining protective cleanup levels or response actions where no ARARs exist, or where ARARs alone would not be sufficiently protective of human health and the environment. Because TBCs are not ARARs, their early identification is not mandatory.

The state permit conditions for the Chino Mine shall be considered TBC materials and considered in the FS for developing remedial alternatives.

Chino had the primary responsibility for identifying federal ARARs for the STSIU. Potential federal ARARs that have been identified for the remediation of STSIU were determined in the RI (SRK 2008) and FS Proposal (Arcadis 2011a) and are presented in Tables 2-1, 2-2, and 2-3. Pursuant to the definition of the term “on-site” in 40 CFR Section 300.5, the area that is considered part of the remedial action is STSIU (see Section 2.5).

2.3 Remedial Action Objectives (RAOs)

This section identifies the environmental media for the STSIU where potentially unacceptable risks were determined to exist through the risk assessments completed during the RI, as well as the constituents determined to be responsible for the potential for unacceptable risk. This section also presents the specific RAOs developed for the STSIU for each media of interest.

RAOs are medium-specific goals designed to protect human health and the environment. RAOs serve to focus an FS and provide context for the overall scope of potential cleanup activities at a site. Each RAO specifies: the contaminant of concern; the relevant exposure routes and receptors; and an acceptable contaminant concentration or range of concentrations for each exposure pathway.

The STSIU RI referenced the completed STSIU HHRA and ERA to determine if any constituents present in the environmental media should be considered Constituents of Potential Concern (COPCs). The sitewide and STSIU-specific ERAs (NewFields 2006, 2008) considered sensitive representative receptors from a number of receptor classes including mammals, birds, plants, and invertebrates. NewFields evaluated direct contact for plants and invertebrates and incidental soil ingestion and food-chain transfer for birds and mammals. The RI also referenced the comprehensive HHRA performed by Gradient (2008) to determine if any chemicals present in environmental media at the site are responsible for potentially unacceptable risk to human receptors in the context of plans for future site use. Accordingly, the human receptor classes evaluated in the HHRA included current resident, future resident, trespasser, construction worker, rancher, industrial worker, recreator swimmer, and trespasser swimmer. Specific pathways considered during the HHRA included direct dermal contact with surface soil, incidental ingestion of surface soil, inhalation of surface soil, dermal contact with surface water, and incidental ingestion of surface water. The risk assessments were implemented according to appropriate guidance and methodologies, which along with the detailed results from the assessments, were previously presented in the STSIU HHRA and ERA reports (Gradient 2008 and NewFields 2006, 2008).

NMED, after reviewing the HHRA and ERA, concluded that arsenic, copper, and iron are potential soil-based risk drivers for at least one human receptor evaluated, and that copper and pCu are potential soil-based risk drivers for at least one ecological receptor evaluated for the STSIU. The Gradient HHRA and NewFields ERA will be discussed in detail in Section 3.1.1.

Based on the findings from the STSIU RI Report, HHRA and ERAs (SRK, 2008a,b, Gradient 2008, NewFields 2006, 2008), the RAOs for the STSIU include:

- Protection of human receptors, as represented by current and future resident or industrial workers, from exposure to arsenic, copper and iron from ingestion of contaminated soil.
- Prevent the ingestion of copper by the small ground-feeding bird (SGFB) receptor at levels that result in unacceptable population-level risks.
- Toxicity to vegetation or other biological elements of habitat should be reduced to levels that allow for a self-sustaining ecosystem and prevent adverse impacts on local wildlife populations or subpopulations. In areas where habitat function is degraded due to toxicity of elevated copper concentrations and/or decreased pH from either smelter emissions or contamination released from tailings impoundments, remedial actions should focus on the restoration of wildlife habitat.
- Restore water quality to water quality objectives that are protective of beneficial uses within reasonable timeframe and maintain existing water quality that complies with water quality objectives. RAOs should reduce the likelihood of contact between surface water and soils/sediments that contain heavy metal contaminants at concentrations that could cause deleterious effects to aquatic receptor populations.

2.4 Pre-FS RAC

In a letter dated September 16, 2010 and then amended via a dispute resolution letter dated March 3, 2011, NMED provided Chino with a Pre-FS RAC for the STSIU (NMED, 2010, 2011). Based upon the information documented in the ERA, HHRA, as well as the comments and input provided from all parties, NMED has determined the Pre-FS RAC values for soil and surface water as discussed below.

Surface Soil

NMED has determined a Pre-FS RAC for metals that potentially pose human health and ecological risk based on the information documented in the ERA, HHRA, and probability analysis. NMED established HHRA Pre-FS RAC values for arsenic, copper, and iron as follows:

- Arsenic: NMED selected the cancer target risk with a Pre-FS RAC of 27 mg/kg. This value is supported by the probability analysis (Arcadis 2010c,d,e) and is consistent with the range of arsenic clean-up levels previously set in New Mexico by USEPA.
- Copper: NMED selected the non-cancer risk human health Pre-FS RAC as previously determined for the Hurley Soils IU of < 5,000 mg/kg copper at private, commercial, and public developed properties.
- Iron: NMED selected the non-cancer risk Pre-FS RAC based on the probability analysis (Arcadis 2010c,d,e) of 100,000 mg/kg.

NMED established ecological Pre-FS RAC values for copper as follows:

- To reduce soil toxicity to plants from copper to pCu ≥ 5 where copper is > 327 mg/kg.
- To reduce soil toxicity to SGFB of 1,600 mg/kg. The SGFB Pre-FS RAC is applicable to the 95 percent upper confidence limit (UCL) of the area-weighted average concentration of copper in surface soil (0-6”) within exposure units in the STSIU. In addition, NMED required monitoring for copper concentrations in surface soil between 1,100 and 1,600 mg/kg.

Based on the final Pre-FS RAC issued in a letter dated March 2011, NMED stated:

> *Since the FS and ROD will be completed consistent with the NCP, new information can be used to refine RACs and selection of alternatives. This is supported by the NCP in §300.430(e)(2)(i) which states “Establish remedial action objectives specifying contaminants and media of concern, potential exposure pathways, and remediation goals. Initially, preliminary remediation goals are developed based on readily available information, such as chemical-specific ARARs or other reliable information. Preliminary remediation goals should be modified, as necessary, as more information becomes available during the RI/FS. Final remediation goals will be determined when the remedy is selected. Remediation goals shall establish acceptable exposure levels that are protective of human health and the environment…” It must be noted that NMED’s pre-FS RACs are equivalent to preliminary remediation goals referred to in the NCP.*”

Thus, Pre-FS RAC are consistent with the use of PRG by EPA in the NCP, and new information can be used to refine the Pre-FS RAC and selection of alternatives. Additional information is provided herein in Section 1.3 and Appendices A, B, C and D. As discussed in Section 1.3, based on discussions and field work conducted with NMED, soil sampling and vegetation community measurements were conducted in 2018 from new agreed-upon locations. Results were incorporated into calculations of DELs and PELs presented in the phytotoxicity study for four soil types (see Appendix C). The average PELs for pCu across the soil types ranged from 2.97 to 4.60, with the highest values in the flat rocky soil category. Based on this new information, the PELs are used to identify acres for remedial alternative evaluation herein. Moreover, percent cover, richness and OAT are used to further identify poor rangeland as described in the approved FS Work Plan (Arcadis 2011a).

In cases where the above criteria overlap for a given area, the constituent which requires the largest remedial footprint will be considered the “risk driver” and the remedial technology will be selected to address this “driver”. The selected remedial technology will be evaluated to confirm that all “non-risk driver” constituents are in compliance with their respective RACs. With the issuance of the Pre-FS RAC, constituents identified in the RI and risk assessment as COPCs are now considered constituents of concern or COCs. The FS and ROD will be completed consistent with the NCP. Final remediation goals will be documented in the ROD.

Surface Water

NMED selected the Pre-FS RAC for surface water based upon the State of New Mexico Standards for Interstate and Intrastate Surface Waters, Part 20.6.4 NMAC for risk to aquatic life. The Pre-FS RAC for all constituents is Part 20.6.4 NMAC, including all approaches and tools listed in the Code which provide options for site-specific application.

Ground Water

NMED discovered a data gap in the RI Report during the preparation of Pre-FS RAC letter. Drainage sediment sample results exceed the NMED Dilution Attenuation Factors (DAF) developed to protect ground water. Although this potential impact was included in the conceptual site model (CSM) and in the risk assessments, NMED requested Chino to further investigate this potential pathway. NMED requested that Chino collect additional samples from all the drainages that currently exceed the DAF 1 as listed in NMED’s Technical Background

Document for Development of Soil Screening Levels, Revision, 5.0 (NMED, 2009) or exceed background concentrations for the following COPCs: arsenic, barium, cadmium, copper, iron, molybdenum, and selenium.

Chino submitted a work plan on October 20, 2010 and NMED approved the work plan on November 10, 2010. Chino implemented the work plan in December 2010 with NMED participation. The samples were analyzed using 1) SPLP and 2) Acid-base Accounting (ABA) and the results were compared to Ground Water Quality Standards to determine if this potential pathway may impact groundwater and if potential remedial alternatives should be developed in the FS. The results showed that there is no risk associated with sediments leaching to groundwater; therefore, groundwater will not be evaluated as part of the STSIU FS. The results from the sampling effort were presented in the *Groundwater Quality Pre-Feasibility Study Remedial Action Criteria for Drainage Sediments* (Arcadis 2011b).

2.5 AOC Study Boundaries

As specifically described in the AOC Scope of Work (NMED, 1994), the STSIU includes all areas containing and proximal to Chino's copper smelter including the slag, all areas containing or which contained facilities ancillary to the primary smelter, and the soil adjacent or impacted by the tailings facility (excluding the Hurley Soils IU). The investigation area is contained in section 31 of T18S, R12W and sections 4, 5, 6, 7, 8, 9, 16, 17, 18, 19, 20, 21, 28, 29, 30, 31, 32, and 33 of T19S, R12W. The above township-range sections, as shown in Figure 2-1, include the town of Hurley, Chino operational area, and all tailings ponds; however, the town of Hurley and the former Hurley Operations Area are excluded from the IU because applicable remediation or closure of these areas are covered under separate regulatory activities. The western extent of the 1994 AOC area is Highway 180, the eastern extent is approximately a quarter mile east of the toe of Tailings Pond 7, and the southern extent is approximately 1 mile south of Tailings Pond 7.

The former Hurley Smelter was decommissioned and demolished in 2007. The Hurley Operations Area is bounded by the Town of Hurley to the west, Whitewater Creek to the northeast, Lake One to the east, and the tailings impoundments to the south. Current land uses adjacent to the former Hurley Operations Area are residential in the towns of Hurley and North Hurley, tailings disposal south of the operational area, and livestock grazing elsewhere. Chino owns the majority of land included in the STSIU and the majority of this land is currently leased for livestock grazing.

The above investigation area has been expanded over the last 15 years as sampling events have delineated the boundaries of the smelter impacted soils with greater accuracy. The current smelter investigation area now includes areas to the north, east, and west of the original Smelter Investigation Unit located in section 31 of T18S, R12W that have copper concentrations greater than the established background value of 327 mg/kg.

3. Description of Current Situation: Soil

The following sections describe the current understanding of the physical characteristics of the STSIU surface soil based on previous field investigations.

- Section 3.1 summarizes the conceptual site model,
- Section 3.2 addresses how the Pre-FS RAC may be applied across the relatively expansive area encompassed by the STSIU as exposure units, and
- Section 3.3 discusses the upland areas that require potential remedial action as a result of the evaluation.

3.1 Conceptual Site Model

The CSM for sources associated with the STSIU was originally presented in the RI Proposal for STSIU (SRK, 2004) as well as in the risk assessments (Gradient, 2008, NewFields, 2006, 2008). Figure 3-1 illustrates a CSM via pathway segments and mechanisms required to understand how potential contamination occurred, including the source, release and transport of mineral processing constituents. Primary sources listed in this CSM are historical mineral processing activities and tailing impoundments including historical and current facilities.

Soils within the STSIU were affected by historical stack and fugitive dust emissions from historical mineral processing activities associated with the former Hurley Operations area and the tailings area. The AOC Background Report (Chino, 1995) identified the primary sources of contamination in the former Hurley Operations Area resulting from historical smelting, milling, concentrating, and handling of copper bearing material. For the tailings area of the STSIU, the tailings impoundments are considered the primary source of constituents of interest that have the potential to affect environmental media. Both historical and currently operational tailing impoundment may have affected surrounding media; however, DP-214, DP-484 and DP-1340 address any groundwater impacts from the historical or current impoundments due to infiltration to groundwater. Other pathways such as historical run-off and fugitive dust emissions transported constituents in tailings to surrounding soil and drainages. Fugitive dust emissions from the tailings ponds occur when high winds mobilized tailings resulting in transport and subsequent deposition of constituents to the surrounding soil.

Prevailing winds tend to be south-easterly (Chino, 1995); therefore, surface soils in areas to the south and east of the former Hurley Operations Area and the tailings impoundments are likely to be the most affected by dryfall from these aerial sources. Following airborne deposition onto soils, metals and other inorganic constituents may be further redistributed by a combination of physical (air and water erosion) and/or chemical (leaching) processes.

Figure 3-1 identifies the following potential release mechanisms associated with affected surface soil:

- Direct Contact: Exposure associated with direct contact with affected surface soil;
- Re-suspension: Mobilization of affected surface soil to air by wind;
- Run-off: Transport of suspended or dissolved constituents in surface water run-off. Potentially affected sediments may be generated as a result of surface water erosion of surface soil;
- Infiltration: Infiltration of surface water through affected surface soil may potentially release constituents of interest from affected surface soil; and

- Absorption: Constituents from affected surface soil may bioaccumulate in garden foods that could be consumed by persons. In addition, grazing animals, either directly or through plant consumption, could ingest constituents from affected surface soil. Constituents could, in turn, be absorbed through consumption of these animals.

The potential exposure routes for current and future human receptors include:

- Inhalation;
- Ingestion of contaminated food items; and
- Direct contact (ingestion and dermal).

The potential exposure routes for current and future ecological receptors include:

- Direct contact (root uptake and incidental ingestion); and
- Ingestion (contaminated biota).

The above potential human health and ecological exposure routes were evaluated in the STSIU HHRA (Gradient, 2008) and STSIU ERA (NewFields, 2008). Since the completion and approval of the risk assessments, the STSIU has been naturally “limed” by the “white rain” event as described in Section 1.3. This natural event has shifted the geochemistry of the soils and affected the bioavailability of contamination in the STSIU, as documented in the *Year 5 pH Monitoring Report for STSIU* (Arcadis 2023).

In addition to the white rain event, historic sources to STSIU were fully reclaimed, as described further below in Section 3.1.2.

3.1.1 Previous Investigations

The upland soil in the STSIU was evaluated in the STSIU RI (SRK, 2008a,b), the HHRA (Gradient, 2008), and the ERA (Newfields, 2008) prior to the development and issuing of the Pre-FS RAC. The following sections summarize the findings of these three reports.

Remedial Investigation

The STSIU RI Proposal was completed by SRK in 2004 and the RI Report was submitted in 2006 and resubmitted in 2008 with supplemental data (SRK, 2008a,b). Surface soil samples were taken at 165 locations in the STSIU during the RI sampling efforts (SRK, 2008a,b).

The RI concluded that copper is the primary metal elevated in surface soils in the STSIU. In addition, arsenic, cadmium, and iron were also detected above the decision criteria, but their respective concentrations largely fall within the range of reference, and elevated concentrations of these metals generally fall within the footprint of copper concentrations. Consistent with conclusions reported in the AOC Background Report (Chino, 1995) and the *Phase II Remedial Investigation Report for the Ecological Investigation Unit* (Arcadis 2001), copper concentrations in surface soil exhibit strong spatial characteristics with decreasing concentrations as distance in the direction of prevailing winds increases (SRK, 2008a).

Human Health Risk Assessment

In 2008, Gradient evaluated the risks to human health posed by constituent concentrations in the STSIU. Gradient calculated both cancer risks and non-cancer hazards for potential receptors on the site. The methodology used for this risk assessment was consistent with USEPA guidelines and used conservative, default assumptions, whenever site-specific data were not available. The receptors evaluated in the HHRA included current and future residents, adolescent recreators, adolescent trespassers, ranchers, construction workers, and industrial workers. The upland risk assessment evaluated exposures to soil, windblown dust in air, and locally produced food items.

Gradient indicated that site exposure could result in unacceptable cancer risks for current and future residents. However, these cancer risks are largely driven by the consumption of locally grown foods. Gradient stated that the “consumption of locally grown food” pathway was evaluated using conservative assumptions and tends to overestimate risk. Gradient also found that 90% of the excess lifetime cancer risk is attributed to arsenic. All other receptors (recreators, trespassers, ranchers, construction workers, and smelter workers) did not have unacceptable cancer risk.

The HHRA indicated that site exposures could result in unacceptable non-cancer hazards for residents in all five exposure areas. However, these non-cancer hazards are also largely driven by consumption of locally grown foods. Gradient stated that the “consumption of locally grown food” pathway was evaluated using conservative assumptions and tends to overestimate risk. Furthermore, all residential non-cancer risks in the STSIU were lower than residential RME non-cancer hazard calculated for the reference area. All other receptors (recreators, trespassers, ranchers, construction workers, and smelter workers) had acceptable non-cancer hazards.

Gradient evaluated copper risks separately using a probabilistic method, only for ingestion of soil. The most sensitive endpoint for copper toxicity is nausea; therefore, copper risks were based on estimating the annual number of nausea episodes that an individual might experience, at a given soil copper concentration. Overall, the industrial worker in the smelter area had the highest copper risk, with an estimated 65 nausea events per year.

NMED established human health RACs for three constituents, including arsenic, copper, and iron, as discussed in Section 2.4.

Ecological Risk Assessment

The Site Wide BERA (NewFields, 2006) was completed and used as the basis to streamline the IU-specific ERA for the STSIU (NewFields, 2008). These ERA reports evaluated the risks from soil to terrestrial receptors. The methodology used for this risk assessment was consistent with USEPA guidelines, and used conservative, default assumptions, whenever site-specific data were not available. The methodology and parameter selection are described in Technical Memo 1 – ERA Workplan and the sampling and analytical approach are described in Technical Memo 2 (Schafer and Associates, 1999a, 1999b). The receptors evaluated in the terrestrial ERA included terrestrial vegetation, herbivorous birds, omnivorous birds, raptors, herbivorous mammals, omnivorous mammals, ruminants, and mammalian predators. The risk assessment evaluated exposures from direct contact, incidental soil ingestion, and ingestion of prey items.

It was concluded that the risks to plants and wildlife were primarily related to elevated copper concentrations and depressed pH in soil (NewFields, 2008). The risks to the SGFB, the most sensitive receptor evaluated, appear to be elevated in the STSIU due to exposure to copper. The potential for risk, for both plants and the SGFB, is greatest in the areas immediately to the east of the smelter and the tailings impoundments and decreases with the increased distance to the east of those features.

Since 2008, when the NewFields STSIU ERA was approved by NMED, there has been further analysis of the risk to the SGFB. The following studies and updated exposure parameters have led to a decrease in predicted exposure levels for the SGFB.

- Ingestion Rate of Food and Soil: The ingestions rates used by NewFields in the ERA were updated to more recent allometric-based values in the literature (Nagy, 2001).

- The dose equation was updated to model all potential dietary intakes in dry weight.
- Insect tissue concentrations: Additional insect tissue was collected in 2010 to supplement the tissue that was collected and analysed for in the ERA. The results of this sampling event are presented in the *Terrestrial Invertebrate Copper Bioaccumulation and Bioavailability Study* (Arcadis 2010a). These results were used to update the relationship between copper in soil and insect tissue and to more accurately estimate bioavailability from insect tissue.

When the above refinements are incorporated into the dose model for the SGFB, there is a decrease in the predicted exposure associated with the SGFB. The approved Site Wide ERA (Newfields, 2006) documents a prediction of population level risk based on the earlier limited data. With the uncertainties in mind, Chino developed and NMED approved the *Terrestrial Invertebrate Copper Bioaccumulation and Bioavailability Study for STSIU* (Arcadis 2010a), and subsequently field data were collected with NMED. The results of the data indicate that exposure levels have changed for the SGFB. If the Site-Wide ERA had been formally amended to include such data, the updated exposure parameters would result in lower LOAEL HQs and would update the conclusions of the Site-Wide ERA (Arcadis 2011d).

As summarized in Section 1.3, the amendment study, pH monitoring report, and draft phytotoxicity report, were submitted subsequent to the approval of the FS Proposal, and all three are referenced herein as Appendices A, B, and C, respectively.

3.1.2 Previous Reclamation and Interim Actions

The Hurley Mill and Smelter were closed and demolished in 1985 and in 2003 and 2007, respectively, and the historical mineral processing operational area was fully reclaimed with 3 feet of borrow fill including slag, improving overall air quality, and eliminating the source of acid and copper to STSIU soils. Closure plans were implemented under DP-1340 for the reclamation of historical tailing impoundments (Tailings Pond 1, 2, B, C, 4, 6E and 6W) (Golder 2013a,b). The Town of Hurley, which is located in the HSIU, was remediated in 2006 and 2007. In addition, also under DP-1340, Condition 90, the Lake One Closure Plan was submitted to NMED in December 2012, approved by NMED, implemented in 2013 (EMC^2 2014). Borrow fill for reclamation was taken from within the STSIU boundaries, outside of the operational footprint as discussed in Section 1.3.

Additionally, interim actions were completed in 2008 and 2012, as summarized in the *STSIU Interim Removal Action Completion Report* ("Golf Course IRA") and the *Supplemental STSIU Interim Removal Action Completion Report ("Railroad IRA")* (ARCADIS, 2009 and Golder, 2013c). Specifically, these areas included the area west of Highway 180, the South Golf Course, the North Golf Course, the Alley Way adjacent to the South Golf Course, the area east of Highway 180, and other sites located at the end of the South and North Golf Courses. The objective of the interim actions were to remove soils where copper concentrations were greater than 5,000 mg/kg (lateral delineation) at 0 – 1" based on the 2005 NMED-approved residential RAC for the Hurley Soils IU (and later formally issued in 2011 as pre-FS RAC for STSIU), as the acres were deemed future residential as extensions of the town of Hurley and fall within the current city limits. Within the areas with higher than or equal to 5,000 mg/kg, soils were removed vertically until the copper concentrations were less than 2,700 mg/kg or resistance met.

Later interim actions were also completed in 2014 and 2019 as summarized in the *STSIU Razorback Ridge Interim Remedial Action Completion Report* (Golder 2015) and *the B-Ranch Interim Remedial Action Completion Report* (Arcadis 2020). The Razorback Ridge IRA is located east of Lake One in areas adjacent to the Whitewater Creek Diversion Channel and James Canyon. The B-Ranch IRA is located adjacent to the reclaimed slag and the

Golf Course IRA with Whitewater Creek bounding the east side of the site. The objective of the IRAs was to remove soils in areas with copper concentrations higher than 5,000 mg/kg, delineated laterally, as per the STSIU pre-FS RAC. As the soil removed from the Razorback Ridge Area was being utilized as borrow fill material, removal depths were at 1 to 2 feet depth and only post removal sampling was performed. Post-confirmation and post-removal data associated with the above-described removals was incorporated into Chino's maps and databases, as summarized in Table 3-2.

3.1.3 FS Proposal Data Collection

The FS Proposal summarized additional sampling needed to refine the potential remedial areas for all constituents that exceed their respective Pre-FS RACs (Arcadis 2011a). Additional soil samples were collected to more accurately define the current extent of contamination for copper and pCu in surface soil. The exact sampling locations and methods were presented in the Upland Sampling Work Plan (Appendix A) of the FS Proposal.

Additionally, exposure units are delineated via desktop evaluation with field verification. The Upland Sampling Work Plan (Appendix A) of the FS Proposal described the methodology that is used to perform rangeland and drainage habitat surveys to better understand the potential habitat units in the STSIU. NMED required that the SGFB copper Pre-FS RAC be applied as a 95UCL area-weighted average over a habitat unit. Through use of vegetation alliance polygons (DBS&A 1999, Newfields 2006), SGFB habitat units are defined for the STSIU and presented herein. Similarly, the pCu Pre-FS RAC is applied as an average concentration over a habitat unit, as described in Appendix D. Datasets and exposure units are described further below in Section 3.2.

3.2 Nature and Extent of Contamination

According to the AOC, the soils of concern in the STSIU are the areas that exceed the Pre-FS RAC values described in Section 2.4 of:

- < 5,000 mg/kg copper at 0-1" bgs,
- 1,600 mg/kg copper surface weighted 95 UCL for a habitat unit for 0-6" bgs,
- 27 mg/kg arsenic at 0-1" bgs, and
- 100,000 mg/kg iron at 0-1".

In addition to the Pre-FS RAC described above, based upon new information submitted herein and summarized in Sections 1.3 and 2.4, pCu less than 5 with soil copper concentration greater than 327 mg/kg for 0-6" bgs as well as richness, cover and rangeland condition (measured with the OAT score) are used to identify acres of soils of concern.

There are three constituents that exceed NMED's Pre-FS RAC for soil in the STSIU. Copper and iron have exceedances of the NMED human health criteria, while copper and pCu fail their respective ecological criteria. Each constituent is described further in sub-sections below.

3.2.1 Arsenic

Of the 165 samples collected for the STSIU RI, there are no exceedances of the human health Pre-FS RAC of 27 mg/kg (Table 3-1). Therefore, arsenic will not be further evaluated in the STSIU FS.

3.2.2 Copper

There have been approximately 450 pre-IRA surface soil samples (0-1” bgs and 0-6” bgs) collected in the STSIU through December 2012. These samples were taken during the following investigations: AOC Background Report (Chino, 1995), Site Wide ERA (NewFields, 2006), STSIU RI (SRK, 2008a,b), pH monitoring (Arcadis 2023), amendment study (Arcadis 2017), phytotoxicity and community study (Arcadis 2018), and the STISU FS Upland Sampling Plan (Arcadis 2011a). The results from the FS Upland Sampling Plan are discussed in Appendix D. About 1,500 samples were collected during four IRAs: Golf Course (Arcadis 2009), Railroad (Golder 2013c), Razorback Ridge (Golder, 2015), and B-Ranch (Arcadis 2020). Table 3-2 summarizes all samples collected in STSIU. All IRA delineation and confirmation samples were analysed using XRF and corrected using the regression equation based on a subset of the samples analysed by a laboratory. The regression equation and methodology were presented in the IRA Completion Reports.[4] All borrow areas, which were excavated at depths of 1 to 12 feet, were assumed to have copper concentrations at background, equal to 327 mg/kg.[5]

The risks from copper in the STSIU are driven by exceedances of the pre-FS RAC for both human health and ecological receptors. The human health risks were evaluated with copper sampled in the 0-1” bgs interval, sieved to < 0.25 mm. The risk to ecological receptors is evaluated using the soil horizon of 0-6” bgs, sieved to < 2 mm. Historically, most copper samples were sampled from the 0-1” bgs interval to determine potential risk to human health. Using the methodology presented in Appendix A of the FS Proposal (Arcadis, 2011a), for ecological evaluations, the copper results from the 0-1” were adjusted to 0-6” using the median ratio between the two depths (0.7 unless in windblown tailing area, where it was 1.5, Table 3-2). This adjustment provided a more robust 0-6” dataset to evaluate the remedial alternatives. The locations and concentrations of the copper samples evaluated in the pre-IRA dataset are shown in Figure 3-2. As presented in Figure 3-2, copper concentrations were the greatest to the east of the historical smelter and decrease with increased distance from the historical smelter’s location. There were also areas of elevated copper on the north, south, and west of the town of Hurley from smelting and other historical mineral processing activities. Similar to the elevated areas to the east, copper concentrations to the north, south and west decrease with increased distance from Chino’s operational area.

As discussed in Section 2.4, the March 3, 2011 NMED Chino AOC Informal Dispute Resolution STSIU memo states that the copper SGFB Pre-FS RAC value of 1,600 mg/kg is intended as the 95UCL area-weighted average concentration within an exposure unit, and the exposure unit should be delineated based on habitat. The habitat polygons represented by the vegetation alliance map developed by DBS&A (1999) (and referenced by NewFields (2006)) were used as habitat units for upland areas (Figure 3-3) as discussed in the approved FS Proposal (ARCADIS, 2011a).[6] During the 2011 field effort, a subset of the STSIU drainages was evaluated to determine if the avian habitat along the drainage banks was different from the adjacent upland. It was determined that the STSIU drainage banks were not significantly different from the adjacent upland (Appendix D); therefore, the existing vegetation alliance polygons that encompass the upland and banks of the drainages were used as the ecological exposure unit for SGFB, without differentiating between upland and banks of drainages.

After determining the best interpolation method for copper, the datasets for each exposure unit for the SGFB were determined by intersecting the ArcGIS interpolated copper Thiessen polygons with the DBS&A vegetation

---

[4] The Razorback Ridge and B Ranch Completion Reports did not report corrected XRF data; however, paired datasets with XRF and laboratory copper results were reported and a regression was developed and used to correct the data reported in Table 3-2.

[5] As part of the borrow excavation, some surficial wind blown tailings were also removed but not sampled. Any older samples previously located in these areas were substituted with 327 mg/kg before performing the interpolation.

[6] Alliance polygon size shifted for several polygons based on updates to the habitat map and an addition of “mine facilities/other” category.

alliances for the post-IRA dataset (includes effect of borrow removal) as shown in Figure 3-4. All Thiessen polygons with either lab or XRF sample results[7] that exceed the human health RAC of 5,000 mg/kg have already been remediated for compliance with the human health RAC.[8] Based on the monitoring criteria for the avian pre-FS RAC, exposure units (or habitat polygons) which intersected a copper Thiessen polygon with a concentration ≥ 1,100 mg/kg were retained for further evaluation.[9] For each retained exposure unit, a 95UCL area-weighted average concentration was calculated, using the percentile bootstrap method.[10] Table 3-3 includes the exposure units that have 95UCL concentrations in excess of 1,100 mg/kg. The colors of the exposure units in Figure 3-5 identify which of these post-IRA exposure units require remedial technology evaluation, additional monitoring, or no further action to be in compliance with the avian pre-FS RAC, depending on the 95UCL copper concentration of the unit. There were no exposure units with 95UCL concentrations exceeding the avian RAC of 1,600 mg/kg. Exposure units in yellow have a 95UCL between 1,100 mg/kg and 1,600 mg/kg and will require additional monitoring for the protection of the small ground-feeding bird (alliance polygons 1-3, 10-16, and 88-15). Exposure units in green do not require any additional action.

3.2.3 Iron

Two of the 165 soil samples collected for the RI and analysed by EPA 6010 exceed the human health Pre-FS RAC of 100,000 mg/kg (Table 3-1). The locations of these samples (SS145 & SS148) are along the eastern border of Tailing Dam 7 as seen in Figure 3-6. The iron results from SS145 & SS148 only slightly exceed the human health Pre-FS RAC with concentrations of 141,000 mg/kg and 123,000 mg/kg, respectively. However, the area encompassing these two sample locations fall within the currently operational Tailing Pond 7 footprint and will be addressed under the CCP and DP-1340. Thus, iron is not retained for further evaluation.

3.2.4 pCu

Cupric ion activity (pCu) was directly measured in 0-6” bgs soil at 17 sites in the STSIU in 1999 and was strongly related (R2 = 0.97) to copper concentrations and pH in the following equation (upland equation from Sitewide ERA, Newfields, 2006):

$$pCu = 7.34+(0.93*pH)-(1.15*\ln[Cu_{tot}])$$

---

[7] Results based on 0-1” and sieved to < 0.25 mm.

[8] There are sample points identified in Table 3-2 with copper greater than 5000 mg/kg where bedrock was noted (where the sample result represents dust that could be wiped off the rock), or steep slope, infrastructure, or ROW was encountered and thus cannot be remediated.

[9] Appendix A of the FS Proposal included Table 3 which summarized vegetation polygons with copper greater than 1,600 mg/kg. The number of polygons was increased to 18 to include those with a maximum concentration greater than 1,100 mg/kg. There were 298 samples across 9,121 acres identified in the FS Proposal representing polygons with maximum concentrations greater than 1,600 mg/kg, and 1,922 samples across 9,760 acres herein representing polygons with maximum concentrations greater than 1,100 mg/kg. Bedrock samples where the sample result represents dust that could be wiped off the rock were removed from the dataset for the bird Pre-FS RAC evaluation. Older sample locations removed via an IRA were changed from the reported result to 327 mg/kg (NMED background value noted in the Pre-FS RAC).

[10] 5,000 iterations (USEPA 2010a) implemented by a macro developed for EXCEL. Several polygons had more samples than the maximum allowed by the macro (29-1, 137-7, 137-8 and mine facilities/other) and the lowest weight samples had acreages binned and a spatially weighted average used so macro could run due to array size. Bedrock sample points were removed in the post-IRA copper dataset evaluation. Samples located in borrow were substituted with background (327 mg/kg). Polygon 1-2 was overlapping a borrow pit on the south side of Hurley and was reclaimed. Polygon 128-7 is a stock tank and the upland surrounding it was added to Polygon 138-8.

This equation was applied to available copper and pH data sampled after the white rain event at 0-6" bgs and sieved to < 2 mm to estimate pCu and its spatial distribution on STSIU (Table 3-4). Post-white rain samples best define areas that might require remediation because they best represent current conditions. Of 155 pCu locations, 102 were sampled in the STSIU after the white rain event. These 102 samples did not fully cover the outer edges of the STSIU, however, and 56 pre-white rain samples were added to fill in the gaps (plots shown in Figure 3-7 and Table 3-4). All pre-white rain samples used to bound the post-white rain samples had pCu > 5 with the exception of a few locations directly north of Hurley and just east of Tailing Pond 7. The use of pre-white rain pCu concentrations to develop the pCu contour map in Figure 3-8 is conservative as there is no new source of acidity and natural attenuation is currently taking place.

As discussed in Section 1.3, the results of the 5-year pH Monitoring Study showed that the 2008 white rain benefitted the STSIU soils by increasing the pH and pCu of the acidic soils, making copper less bioavailable. The increase in pCu led to a decrease in the uptake of copper into living organisms and improved wildlife and rangeland habitat as a result. In addition, the potential of STSIU soils to generate acid is consistently low in most areas (Arcadis 2017 in Appendix B).

Using the above calculated pCu dataset, pCu contours were developed using natural neighbor[11] interpolation as shown in Figure 3-8. As proposed in the FS Proposal, Chino selected the pCu exposure units to be the polygon boundaries defined by combinations of different soil and vegetation types. These are the same boundaries that were used for the rangeland condition analysis in Woodward Clyde (1997) and thus are referred to as "rangeland polygons" (Figure 3-9). Only rangeland polygons that intersected average pCu < 5 and copper > 327 mg/kg (i.e., below the Pre-FS RAC) that failed the criteria below for rangeland (OAT score) and wildlife habitat quality (richness and cover) were retained for further remedial evaluation. The criteria remove polygons from remedial consideration where the destruction of the existing vegetation and inevitable increase in soil erosion associated with remediation could lead to a loss of long-term environmental benefits to the vegetation, causing more harm than good.

- Except for bedrock, if the observed apparent trend (OAT) score of the rangeland polygon was ≥ 22 for all soil categories, the polygon was considered to have "fair-good" rangeland condition (acceptable condition) and, therefore, was excluded from further evaluation. If the OAT score was < 22 (or < than 13 for bedrock, see Attachment A of Appendix D), the polygon's rangeland condition was considered "poor" and it was retained for further evaluation. The cutoff of 22 was based upon data in 1997 rangeland condition datasheets (see Woodward Clyde 1997) showing most rangeland polygons had fair to good condition with OAT ≥ 22 on STSIU, as described in the approved FS Workplan (Arcadis 2011a). The 2011 OAT scores (see Appendix D) were used to determine current rangeland condition for this FS.
- If the percent vegetation cover of a rangeland polygon was ≥ a targeted percentage of a reference mean area value based on variability of the background value of its soil category, the polygon was considered to have "acceptable" cover for wildlife habitat (see Attachment A of Appendix D for details). Flat granular soil, flat rocky soil, bedrock (> 60%), and steep slopes are the four soil categories with different targeted percentages. Unacceptable polygons based on cover were retained for further evaluation.
- If the vegetation species richness of a rangeland polygon was ≥ a targeted percentage of reference area mean values based on variability of the reference values of its soil category (Attachment A of Appendix D),

---

[11] Natural Neighbor was used, rather than kriging discussed in the Work Plan, because the final dataset supplemented with 2011 data did not produce a semi-variogram that met assumptions of a kriging model, as discussed in Appendix D.

the polygon was considered to have "acceptable" richness for wildlife habitat. Unacceptable polygons were based on richness were retained for further evaluation.

OAT scores, percent vegetation cover, and species richness for each polygon were obtained using remote-sensing-based maps developed from Ikonos imagery that covered the site on September 4, 2011 (Appendix D). These maps were classified into two categories: acceptable and unacceptable, as discussed above. evaluated for accuracy using the percent cover and species richness that were sampled in the field on 100 ft^2 plots and the OAT score data collected on 200-m transects that were alongside the plots in 2011, 2014, or 2018 (plots are shown in Figure 3-10, see Appendix D for details). All field sample locations had been grazed, as almost all of the STSIU has been grazed, and therefore the criteria for success was a comparison to reference plots.[12]

All plots with field data for vegetation cover and species richness were used to evaluate map accuracy because the locations were independent of the high and low value endpoints used to calibrate the vegetative cover model and training sites for richness. However, for rangeland condition (OAT score), 3/4 of the ground samples were used for training and thus only 1/4 of the samples were used for accuracy assessment (see Appendix D). The accuracy of the OAT score, vegetation cover, and species richness maps in identifying the two classes (acceptable vs. unacceptable) was relatively good at 88%, 74%, and 71%, respectively, meeting the goal of at least 70% accuracy (Tables 3-5, 3-6, and Appendix D).

For the final classification of a rangeland polygon as containing vegetation that may have been degraded in quality by pCu, the polygon had to be rated unacceptable for the OAT score (rangeland condition) and unacceptable for either richness or cover (wildlife habitat quality). The retained rangeland polygons classified as unacceptable (overlaid on the four soil categories) with pCu lower than the pre-FS RAC where copper is > 327 mg/kg are shown on Figure 3-11. The mapped acres in Figure 3-11 with pCu < 5 that had greater than 327 mg/kg copper were 796 acres of bedrock, 218 acres of steep sloped areas (steep slope defined as > 13%), and 415 acres of flat rocky soil areas. Because vegetation response to pCu varies by soil category and its buffering capacity (see Appendices C and D), the retained rangeland polygons were further evaluated as to whether their average pCu exceeded their PEL based on the polygon's soil category, as shown in Table 3-7 and described in Appendix D. If a retained rangeland polygon had an average pCu ≥ its PEL, it was removed from further analysis.

The pCu contour map in Figure 3-8 represents the post-white rain conditions before more recent interim actions and soil removals described earlier occurred. Areas reclaimed or with wind-blown tailing or borrow material removal were assumed to have pCu above the pre-FS RAC of 5 because depths over one to 12 feet were excavated (copper and pH effects are in shallower layers). These areas and associated polygons dominated by these areas were excluded from further analysis.

The retained rangeland polygons after accounting for areas already reclaimed or removed are largely dominated by flat rocky areas and exposed bedrock (Figure 3-11), with the latter mostly classified as Mountain Mahogany Shrubland Alliance in the DBS&A vegetation alliances. To further evaluate the bedrock areas, Chino worked with NMED in September 2012 to compare bedrock areas within the STSIU to an agreed upon reference bedrock area outside of the STSIU. However, NMED later deemed the area selected to not to be an adequate bedrock

---

[12] Based on the FS work plan that specified grazed plots will be evaluated for habitat quality by comparing to reference plots. The plots included one north- and one south-facing grazed "wildlife reference" plot and an "overgrazed reference" plot (Figure 3-13). However, the "wildlife reference plot south" and "overgrazed reference" plot were downgraded to site plots with "de minimis" impacts after reviewing their pCu estimates when chemistry was later collected (see Appendix C and D) and were not used as reference plots. Eight additional reference plots, representing the four major soil categories on the site were sampled in 2018 and, along with previously collected data on two other reference plots (SPS- and wildlife reference plot north in Figure 3-11) were used to estimate target thresholds, as described in Attachment A of Appendix D.

reference area because it was found to have pH lower than background (Appendix D). A reference area study was initiated in 2018 to identify adequate references areas east of the former smelter that would represent all four soil categories, including bedrock (see Attachment A to Appendix D). Using the observation and numeric results from that study, Chino excluded three of the four soil categories (including bedrock) from further consideration for remediation, as their mean concentrations in all exposure units were less than their respective PEL. The exception was the flat rocky category, which had exposure units exceeding the rocky flat PEL (Table 3-7). Thus, the retained rangeland polygons were all in flat rocky soils with average pCu ≤ 4.6, which is the flat rocky PEL, and the acreage of these polygons totaled 113 (Figure 3-12).

3.3 Soil Exposure Units to be Evaluated for Remedial Alternatives

This FS evaluates all areas where Cu in soil is greater than 1600 mg/kg, Cu in soil is within the monitoring range of 1100 – 1600 mg/kg, and pCu in soil is equal to or less than the PEL for the soil category (which is 4.6 for flat rocky soils) and considers which technologies are feasible. There are no polygons with a 95UCL area-weighted average for Cu greater than 1,600 mg/kg and there are three polygons carried forward for monitoring: 1-3 (23 acres), 10-16 (71 acres), and 88-15 (46 acres). There are 113 acres carried forward for the pCu evaluation.

4. Description of Current Situation: Surface Water

4.1 Conceptual Site Model

As discussed in the AOC Background Report (Chino, 1995) and the STSIU RI (SRK, 2008a,b), the surface waters[13] and drainages in the STSIU include Bolton Draw, Rustler Canyon, Martin Canyon, and other un-named tributaries of Whitewater Creek and Lampbright Draw. Previous investigations including the RI and ERA have noted the majority of these drainages are considered ephemeral, with surface water flow generally occurring during and immediately after a precipitation event. Other than these drainages, the remaining surface water bodies present in the STSIU are livestock watering tanks. The livestock tanks are generally designed to catch surface water run-off and/or spring or well water, and to hold water for extended periods of time.

Fate and Transport of COCs in STSIU Drainages

The primary sources of surface water impacts in the STSIU drainages are due to the presence of COCs in surface water runoff and leaching of COCs from sediments (Figure 3-1).

Surface Water Run-off

For the STSIU drainages, runoff from the upland environment is considered to be a source of potential COC impacts to surface water. COCs from COC-affected soils, from either smelter emissions or fugitive dust, have the potential to be sorbed to/incorporated into suspended particles or dissolved in runoff during precipitation events, leading to increased total and dissolved surface-water concentrations of COCs in the receiving drainages.

Leaching from Sediments

STSIU surface water also has the potential to be affected by the remobilization of COCs from sediments in drainages during stream flow events. Constituents in COC-affected sediments, derived from smelter emissions, historical upland runoff, or fugitive dust, may be remobilized during precipitation events, leading to possible increased total and dissolved surface water COC concentrations in the receiving drainages. In addition, leaching of COCs from COC-affected sediment may occur during times when water is present in a drainage after a storm event.

The leaching potential of sediments in STSIU drainages was evaluated for samples collected at select locations within the STSIU during a December 2010 sampling event, and the results were reported in the *Groundwater Quality Pre-Feasibility Study Remedial Action Criteria for Drainage Sediments* (ARCADIS 2011b). These results demonstrate that, with the exception of copper, sediments in the STSIU drainages do not have the potential to leach COCs to surface water at concentrations that might adversely affect the surface water quality at concentrations above acute aquatic life criteria.

Summary

The primary mechanisms for loading of COCs to surface water in STSIU drainages is transport of metals in hill slope runoff (dissolved COCs as well as COCs associated with soil/sediment) derived from COC-affected soil in the STSIU. Since sediments in drainages are derived from hill slopes above the drainage, the presence of COCs in hill slope runoff, surface water, and sediments are intimately linked.

---

[13] The term “surface waters” is used in this document to reflect the common meaning of the term, not any legal meaning. Use of this term is not intended to imply that there has been a determination that any particular surface water or drainage constitutes a “surface water of the state” or “waters of the United States.”

Fate and Transport of COCs in Stock Tanks

Stock tanks that receive the majority of their water from surface runoff are a key focus for the CSM because the COC sources described above for surface water will affect the quality of water in the stock tanks. Stock tanks might also receive water from springs or windmill-pumped groundwater, but these tanks do not have a large surface-water runoff component. The water quality in stock tanks may also be affected by the potential regeneration of COCs stored in stock tank sediments.

Surface Water Inflow

Stock tanks receive the majority of their water from surface drainages, which in turn receive the majority of their water from surface runoff. As stated above, there is potential for COCs in soils to be sorbed to/incorporated into suspended particles or dissolved in runoff during precipitation events. In addition, leaching of COCs from drainage sediments and mobilization of COC-affected sediments may occur during the brief period of time when stream flow occurs. These mechanisms may lead to input of dissolved and solids-associated COCs to the stock tanks during runoff events.

Cycling of COCs from Sediments

For stock tanks, the cycling of COCs from sediment to surface water may present a continued source of COC impacts to stock tank surface water. If there is no outflow from a stock tank, all COC-affected sediments transported to a stock tank during a runoff event will accumulate in the stock tank. These COC-affected sediments may present a long-term COC source for stock tank surface water. When a new inflow event occurs, the already present mass of COCs in the stock tank is increased by the constituents present in the incoming surface water. The combination of COC-affected surface water and the remobilization of COCs from COC-affected sediments in the stock tanks may result in the potential for COCs in stock tank water to exceed surface water criteria.

Summary

The majority of the mass of COCs in stock tank surface water is derived from inflow during runoff events. Cycling of COCs from COC-affected sediments that accumulate in the stock tanks may result in release of additional COCs to surface water in the stock tanks.

Surface Water Conceptual Site Model

STSIU surface water, contained in drainages and stock tanks, has the potential to be affected by runoff interacting with COC-affected surface soil and sediment during storm events, and ongoing leaching of COCs from COC-affected sediments during times when water remains within a drainage or stock tank. The CSM for STSIU surface waters (Figure 3-1) identified the following potential exposure pathways associated with COC-impacted surface water:

- Direct Contact: Exposure associated with direct contact with affected surface water;
- Ingestion: Exposure associated with ingestion of affected surface water; and
- Absorption: COCs from affected surface water might bioaccumulate in foods that could be consumed by grazing animals. COCs could, in turn, be absorbed through consumption of these animals.
- The potential exposure routes for current and future human receptors include:
- Direct contact (ingestion and dermal).

The potential exposure routes for current and future ecological receptors include;

- Direct contact (dermal contact);
- Ingestion (drinking water); and
- Absorption (diet-borne exposure).

The above potential human health and ecological exposure routes were evaluated in the STSIU human health risk assessment (HHRA; Gradient, 2008) and ecological risk assessment (ERA; NewFields, 2006, 2008).

4.1.1 Previous Investigations

Remedial Investigation

The STSIU RI was completed in 2004, and then revised with the inclusion of new data and resubmitted in 2008 (SRK, 2004; SRK, 2008a). Twenty-four surface water samples were collected at 16 locations in the STSIU and were used to evaluate surface water quality during the RI (SRK, 2008a). Those results were presented in the Addendum to the RI (SRK, 2008b).

During the RI sampling, aluminium, barium, beryllium, boron, cadmium, calcium, cobalt, copper, iron, lead, manganese, molybdenum, nickel, vanadium, and zinc were detected in STSIU surface waters. Of these detected constituents, only cadmium, copper, and lead were detected at concentrations that exceeded the chronic aquatic life criteria (SRK, 2008b). Lead concentrations were not detected above acute aquatic life criteria. Cadmium concentrations exceeded acute criteria in three drainage locations and two stock tanks. Copper concentrations were consistently above acute criteria in drainage and stock pond locations.

Human Health Risk Assessment

The HHRA (Gradient, 2008) evaluated data generated from surface water samples collected within the STSIU. The risk assessment calculated cancer risks and non-cancer hazards for potential receptors on the site. The methodology used for this risk assessment was consistent with USEPA guidelines and used conservative, default assumptions whenever site-specific data were not available. Gradient evaluated two scenarios, the recreational swimmer and the trespasser swimmer, to determine the potential risk from exposure to STSIU surface water.

Gradient determined that site exposure to surface water did not result in unacceptable cancer risks or non-cancer risks for either the recreational swimmer or the trespasser swimmer scenarios for any COCs identified for the STSIU.

Ecological Risk Assessment

The ERA (NewFields, 2008) evaluated the risks from surface water to aquatic receptors. The methodology used for this risk assessment was consistent with USEPA guidelines and used conservative, default assumptions, whenever site-specific data were not available. The receptors evaluated in NewFields' ERA included amphibians, aquatic invertebrate communities, and fish communities. NewFields only evaluated direct contact exposure for the above aquatic receptors.

The ERA showed that where surface water exists in the STSIU, the COCs of most concern were cadmium, copper, and lead (NewFields, 2008). These three constituents exceed the chronic aquatic life NM WQS and/or the selected amphibian TRVs (Harfenist et al. 1989; Schafer and Associates 1999a) at one or more RI surface water locations.

NewFields (2008) concluded that where water is present in the STSIU, copper concentrations are elevated above acute and chronic water quality criteria at most locations. Risks to aquatic life from copper in surface water are predicted for the limited aquatic habitat within the STSIU. However, the risks to aquatic receptors from chemical exposure need to be qualified given the overall physical quality of the aquatic habitat. Without persistent aquatic habitat in the area, aquatic life is limited to invertebrate species that breed relatively rapidly in water and to potentially breeding amphibians and their larval offspring, particularly in the stock tanks. Therefore, as stated by NewFields (2008), the risk estimations presented for aquatic life are highly uncertain.

Remedial Investigation Technical Memorandum

The STSIU RI Surface Water Sampling and Analysis of Rainfall Pools Addendum was completed in 2008 (Chino, 2008). Seventeen surface water samples were collected at surface water drainage and stock tank locations in the STSIU. These samples were used to evaluate occurrence of select metals (aluminium, cadmium, copper, iron, lead, and manganese) within different size fractions based on filter pore size and to assess potential associations of metals with dissolved organic matter.

During the RI Addendum sampling, all of the analysed metals were detected in surface water samples, but only aluminium, cadmium, and copper were detected at concentrations that exceeded the chronic aquatic life criteria (Chino, 2008). Aluminium and cadmium were primarily associated with particulate form and were mostly excluded by filtration with 0.45 micron filter pore size. Concentrations of copper generally decreased with decreasing filter size fraction. However, ultra-filtered (~0.001 micron effective pore size) copper concentrations exceeded aquatic life criteria for about one half of the locations. Copper concentrations were positively correlated with dissolved organic carbon (DOC) concentrations, suggesting that copper may be bound with DOC and thus may have a lower toxicity. Based on these results, a more formalized surface water toxicity study was undertaken, as described in the following section.

Water Effect Ratio Study

As discussed in Section 1.3, Arcadis conducted a copper WER study for the STSIU surface waters in 2011 and results from the WER study were described in the *Development of Site-Specific Copper Criteria Interim Report* submitted to NMED in March 2013 (Arcadis 2013a). A site-specific copper WER model was subsequently developed to derive adjusted copper criteria in STSIU surface waters in the *Revised Site-Specific Copper Toxicity Model Report* submitted to NMED in October 2013 (Arcadis 2013b). The site-specific criteria for STSIU surface waters were adopted by NMED and are contained in NMAC §20.6.4.809.

2010 Wet Season Survey

Before the WER study work plan was developed, a preliminary 2010 Wet Season Survey was conducted to gain a better understanding of water persistence, copper toxicity, and water chemistry variability in the STSIU surface waters (Arcadis, 2013a). A total of 12 STSIU surface water samples were collected in that study (see Figure 4-1). Surface water samples collected were analyzed for a complete set of water chemistry, including parameters such as total and dissolved organic carbon, alkalinity, and total dissolved solids. Previous site investigations included only a limited number of chemical parameters, which precluded estimation of site-specific metal toxicity using predictive models such as the BLM.

Expedited Use-Attainability Analysis

In 2011, ARCADIS conducted an expedited Use Attainability Analysis based on NMED SWQB’s Hydrology Protocol to determine the appropriate hydrologic regime of STSIU surface water drainages. Hydrologic classifications of STSIU drainages were proposed in the *Application of the Hydrology Protocol to STSIU Drainages* report submitted in October 2012 (Arcadis, 2012). The revised hydrologic classifications were accepted by the New Mexico Water Quality Control Commission without comment. The hydrologic classifications of STSIU drainages are depicted in Figure 4-2. Non-ephemeral drainages include Rustler Canyon, Martin Canyon, Bolton

Canyon, and immediately downstream of Ash Springs. All other STSIU drainage areas are designated as ephemeral.

Surface Water Runoff Quality and Duration Sampling

Appendix E documents the collection and analysis of surface water runoff samples proposed in the STSIU FS Proposal (Arcadis 2011a). The objectives of the surface water runoff investigation included providing additional surface water quality data to support refinement of the conceptual site model and to support the STSIU FS. The objectives of the sampling also included defining the duration of flow and presence of water to support classification of drainage channels in the STSIU. However, the data associated with the duration of flow and presence of water was used in the expedited UAA described above and is thus not included in Appendix E.

As described in Appendix E, both dissolved and total concentrations of metals in stormwater samples were typically higher in samples collected from stormwater samplers installed at higher elevations above the creek channel. This may be due to a longer contact time between runoff and COC-containing soil and sediment or may be due to greater entrainment of COC-containing sediments at higher flows. Concentrations of total metals were generally substantially higher than concentrations of dissolved metals. Most samplers contained substantial quantities of sediment entrained within the samplers and the sample bottles at the time of sample retrieval and the presence of these sediments may have resulted in elevated concentrations of total metals in the stormwater samples. These sediments coupled with the uncertainty regarding the amount of time samples were in the sample bottles prior to retrieval introduced uncertainty in the quality of the data. Because of this, the data in Appendix E were evaluated qualitatively to guide the refinement of the conceptual site model.

4.1.2 Other Activities

Rangeland Improvements

Chino and their lessees periodically perform maintenance activities on the rangelands lying within site boundaries, including removing earthen stock tanks that are no longer required either because they are no longer used or because they are redundant due to other stock tanks located nearby. As part of these rangeland improvements, stock tanks 15, 26, 29, and 60 were removed between 2013 and 2022 and were not replaced.

Additionally, the approximately 230-acre drainage basin feeding stock tank 06 is in the process of being improved to provide for stable stormwater conveyance to the tank inlet. The drainage channel upgradient of the tank is being improved for approximately ½ mile, beginning at stock tank 06 and extending northeast to the railroad crossing immediately west of the intersection of North Hurley Road and A Street. In addition, five check dams are being installed along the drainage to slow stormwater flows entering stock tank 06. These improvements will achieve their desired effect and an improvement to water quality is also expected.

4.2 Nature and Extent of Contamination

Using the results presented in the 2008 RI Addendum, six constituents exceeded a surface-water criterion in the STSIU (SRK, 2008b). Aluminum, cadmium, copper, nickel, silver, and zinc all had exceedances of their respective chronic aquatic life NMWQC, and nickel is the only constituent that did not exceed its respective acute aquatic life NMWQC. However, because the exceedances of the acute NMWQC for aluminum, cadmium, silver, and zinc are insignificant when compared to those for copper, and that any measure taken to address copper in STSIU surface water would also address the exceedances of these metals, copper is the constituent of focus for STSIU surface water.

Since acceptance of the RI, HHRA, and ERA in 2008, New Mexico updated their water quality criteria during the 2010 triennial review. This nature-and-extent section is based on the most recent §20.6.4.900I NMAC.

As described in Section 4.2, additional STSIU surface-water studies were completed after the RI Addendum report was accepted. These studies include the Wet Season Survey conducted in 2010, the Criteria Adjustment Study conducted in 2011, and the Expedited UAA Study and Surface Water Runoff Quality and Duration Study conducted in 2011. Metal concentration data collected during the Criteria Adjustment and Wet Season studies are included in this nature-and-extent section. Copper WERs calculated in accordance with NMAC §20.6.4.809 are also considered herein for evaluating the nature and extent of copper contamination. Based on hydrologic classifications shown in Figure 4-2, chronic aquatic life criteria are only considered for the non-ephemeral drainages, whereas acute criteria are considered applicable to the ephemeral drainages.

4.2.1 Copper – Surface Water Drainages

Figure 4-3 presents a summary of copper compliance and areas of potential concern based on the site-specific criteria and the revised hydrologic classifications for STSIU surface waters described in Section 4.1.1. Table 4-4 includes the WERs used to evaluate the nature and extent of copper contamination in the drainages included on Figure 4-3. Ephemeral streams are shown on Figure 4-3 as dashed lines and sections of drainages that are non-ephemeral are shown as solid lines. Recognizing that aquatic habitat in STSIU surface-water drainages consists entirely of isolated and distal pools in bedrock sections of drainage channels (with the exception of Stock Tanks), Figure 4-3 also distinguishes the alluvium-dominated channels as white-dashed drainage lines. This depiction is intended to highlight drainage areas in which significant pool habitats do not occur due to substrate limitations. The green drainage lines (dashed and solid lines) shown in Figure 4-3 represent drainage areas in which copper contamination is not expected to be of concern in drainage pools based on compliance with the NMAC §20.6.4.809 based on the WERs included on Table 4-4.

Two surface water drainage locations in the STSIU exceed the hardness-adjusted acute aquatic life NMWQC for copper, both of which are in the D-3 Drainage. The HQ for both these exceedances were approximately 8.8. The WER-based Acute HQs are < 1 in samples associated with Lucky Bill Canyon, all but one sample in Martin Canyon, all but one sample in Rustler Canyon, three samples in C-1 Drainage, one sample in C-2 Drainage, three samples in D-1 Drainage, two samples in D-2 Drainage, Lampbright Draw and B and G Drainages, between 1 and 2 in samples associated with one sample in Martin Canyon, one sample in A Drainage, one sample in C-1 Drainage (upgradient of Bolton Canyon Confluence), one sample in D-1 Drainage, and one sample in D-2 Drainage, and above 2 in samples associated with one sample in Rustler Canyon, one sample in C-1 Drainage (downgradient of Bolton Canyon Confluence), one sample in C-2 Drainage, and all three samples in D-3 Drainage (Tables 4-5 and 4-6).

4.2.2 Copper – Stock Tanks

Water chemistry has been evaluated for some of the STSIU stock tanks during previous Site investigations, including the STSIU ERA, STSIU RI, and Wet Season Survey, and from select stock tanks in 2021. The STSIU stock tanks consist of concrete or steel tanks that receive water from springs or windmill-pumped groundwater, and earthen tanks that receive the majority of their water from surface runoff. Earthen tanks in STSIU are typically located in surface water drainages and thus collect water from upgradient drainage channels during precipitation events. A few earthen tanks, however, are located outside of drainage channels and receive overland flow directly from adjacent upland areas instead of upgradient drainage channels. Figure 4-4 shows the current and historical locations and type of known STSIU stock tanks and distinguishes individual tanks of potential concern based on the WERs, as described below.

Consistent with the surface water drainage evaluation, NMAC §20.6.4.809 is used herein to evaluate the nature and extent of copper contamination in stock tanks. As indicated in Figure 4-4 and Table 4-7, earthen stock tanks are the major focus of this evaluation because these tanks receive their water from surface runoff, which can potentially be contaminated by upland COC sources (in contrast to steel and concrete tanks that receive groundwater via springs or windmill pumps). Surface water chemistry data are available for 11 earthen stock tanks, which includes the majority of earthen stock tanks located in the general area of potential concern based on proximity to the historic smelter location (i.e., within subwatersheds A through D) (Figure 4-4; Table 4-7). WERs determined in drainage pools are expected to represent conservative estimates of potential WERs for stock tanks because organic carbon, which greatly mitigates copper toxicity, is generally greater in stock tanks than in surface water pools (due to additional organic matter input from livestock use and aquatic vegetation).

Application of NMAC §20.6.4.809 for the stock tanks results in only marginal exceedances of the adjusted copper criteria (i.e., the greatest adjusted acute HQ is 5.86 in the west drainage stock tank; Table 4-7). As shown in Table 4-7, adjusted copper HQs were calculated for each stock tank using the watershed-specific WERs and the STSIU WER. For stock tanks that were sampled multiple times throughout previous investigations, geometric mean adjusted copper HQs were also calculated to provide a more robust estimate of tanks of potential concern. Using the above methodology, stock tanks 6, 15, 26, 29, and 60 were determined to have concentrations of potential concern to aquatic life (Table 4-7). However, stock tanks 15, 26, 29, and 60 were removed between 2013 and 2022 as part of rangeland improvements, as discussed in Section 4.1.2, and are thus not considered further.

4.3 Surface Water Locations to be Evaluated for Remedial Alternatives

Drainages

Surface water locations described above as areas of potential concern to aquatic life uses will be evaluated for remedial alternatives. This includes the yellow drainage areas shown in Figure 4-3. As described above, potential areas of concern may need to be revised based on the ongoing development of copper SSC.

Stock Tanks

Stock tank 6 was determined to have concentrations of potential concern to aquatic life uses and will be evaluated for remedial technologies.

5. Identification and Screening of Potentially Applicable Technologies

5.1 Soil

As part of the FS Proposal, a range of potential soil remedial technologies have been identified and summarized for the upland areas of the STSIU. In 2006, an extensive literature search was conducted consisting of a review of over 500 abstracts related to potential soil remedial technologies for treatment and/or removal of the primary constituent of concern for the site (copper). As a result of this review, 12 technologies have been identified and included in this FS as Table 5-1 for a preliminary screening and evaluation. The preliminary screening and evaluation of the potential soil remedial technologies has been performed to determine which remedial technologies should be retained for consideration as part of the FS alternatives analysis, which will include a comprehensive alternatives evaluation for remedial alternatives for the site. The preliminary screening of each remedial technology is based on USEPA Guidance for Conducting Remedial Investigations and Feasibility Studies under CERCLA (USEPA, 1988) and includes an evaluation of the effectiveness, implementability, and cost. Potential use of institutional controls, consistent with CERCLA guidance (EPA 2010) may be warranted for implementation of specific remedial technologies as described below.

Based on the preliminary screening conducted in the FS Proposal only a brief summary of the technology is presented, with a summary of the effectiveness, implementability and cost presented in Table 5-1, if the remedial technology is considered viable, it will be retained for consideration as part of the site-wide remedial alternatives analysis in Section 6.

A brief explanation of these soil remedial technologies described below and a preliminary screening of each technology in presented in Table 5-1.

5.1.1 No Action

This remedial technology consists of leaving the site soils in their current condition without performing any soils/vegetation removal or treatment, engineering controls, or institutional controls as part of the remediation efforts. This technology is provided as a baseline for screening other technologies and is summarized as Technology No. 1 in Table 5-1.

Screening Result

No Action is being retained as a baseline for comparison with other remedial technologies in the FS and for potential use in conjunction with other technologies where implementability may be low.

5.1.2 Monitoring

This remedial technology consists of leaving the site soils in their current condition without performing any soils/vegetation removal or treatment, engineering controls, or institutional controls as part of the remediation efforts. As part of this technology, a monitoring program would be implemented to observe and document the occurrence of natural attenuation of site contaminants. Monitoring would include collection of qualitative and quantitative samples of STSIU media such as surface soils, vegetation and other biotic media. This technology is provided as a baseline for screening other technologies and is summarized as Technology No. 2 in Table 5-1.

Screening Result

Monitoring is being retained as a baseline for comparison with other remedial technologies in the FS and for potential use in conjunction with other technologies where implementability may be low.

5.1.3 Excavation and Reuse

This remedial technology consists of removal of soils with contaminants above the soil pre-FS RAC levels located 0- to 1-inches to 6-inches bgs, depending on the potential receptor. Depth of potential removal could vary depending on site features such as the presence of bedrock. Final lateral and vertical removal extents would be determined during the remedial design. This technology would remove soils considered to be impacted for final onsite management at the waste rock stockpiles or for future use as soil fill material for the Chino Mine tailings pond closure activities or other operational areas of the site. This technology is summarized as Technology No. 3 in Table 5-1.

Screening Result

Soil excavation could be applied at the site for the overall site-wide remedy or applied at targeted locations with higher concentrations of contaminated soils in conjunction with another technology. Although this technology may not be implementable at all areas, this technology is being retained due to its high effectiveness at reducing site contaminants.

5.1.4 Excavation and Disposal

This remedial technology consists of removing soils above the soil RAC levels in the same manner as described in the excavation and onsite management remedial technology described in Section 5.2. However, instead of final onsite management of soils at the waste rock stockpiles or re-using the removed soils for fill material in the operational areas of the site, the soils would be disposed of at an offsite commercial disposal facility.

Removed soils would be characterized in accordance with RCRA regulations to determine final offsite transportation and disposition requirements. This technology is summarized as Technology No. 3a in Table 5-1.

Screening Result

Soil excavation could be applied at the Site for the overall site-wide remedy or applied at targeted locations with higher concentrations of contaminated soils in conjunction with another technology. This technology would only be implemented on a limited or case-by-case basis, in select areas. Therefore, this technology is not being retained for development of remedial alternatives due to the high costs compared to excavation and re-use.

5.1.5 Soil Amendments – Limestone and/or Organic Matter

Many soil amendment technologies exist for reducing metals bioavailability, toxicity, and mobility in soils. They rely on changing soil chemistry to affect the solubility or mobility of site contaminants within the soil column, and/or improve vegetative cover or speciation. Several soil amendments are described further below including, pH adjustment via lime addition and/or organic matter, tilling (Section 5.1.6), ferrihydrite (Section 5.1.7) and chelating agents (Section 5.1.8). The pH adjustment and/or organic matter addition technology is summarized as Technology No. 4a in Table 5-1. Arcadis (2017) indicates that liming is recommended for soils with pH < 2 but liming is not that helpful above that pH, and soils pH identified herein are not less than pH 2. Organic matter was not recommended after the amendment study was completed because cow manure brought in weedy plants that degraded the habitat (however, other forms of organic matter could be considered).

As included in the Amendment Study Work Plan (Arcadis, 2008a), data collected over the five years of monitoring will be assessed to determine if a particular amendment, or combination thereof, can be successfully applied to particular areas at the Site.

Screening Result

Soil amendment using lime or organic matter will be retained as a remedial technology to be considered as part of the comprehensive remedial alternative for further evaluation in the FS.

5.1.6 Soil Amendments – Tilling

Soil mixing by using mechanical tilling technology is being evaluated as part of this FS for use at the site as part of the comprehensive remedial alternative. This technology does not include the addition of other amendments such as lime and/or organic matter; however, the subsurface soil at STSIU may include Gila Conglomerate Formation which has high alkalinity and geochemistry that may serve as a naturally-occurring amendment. Tilling will be conducted in a similar manner as performed in the soil amendment study. Initially, the ground surface vegetation is cleared and grubbed using a bulldozer and/or excavator. Following vegetation clearing, the tilling is conducted using a 140 blade (or similar) attached to a bulldozer to mix to a pre-determined depth of soil. In areas requiring soil mixing with limited access to larger equipment, hand tilling equipment can be used as an alternative to the bulldozer to mix soils. Tilling is less intrusive in general; it lowers disruption to habitat and lowers carbon footprint compared to alternatives relying on excavation.

Tilling has the potential to provide additional attenuation of metals and to raise pH conditions to more neutral pH conditions pending existing pH levels within the soil treatment area being tilled. Plant coverage, pH, and soil chemistry would be monitored post-tilling operations. As part of the remedial design phase, additional soil sampling (contaminant levels and soil chemistry) within the soil treatment column would be conducted to determine if tilling alone would be appropriate technology and what is the appropriate soil mixing depth within each soil treatment area to raise pH conditions. The soil amendments - tilling technology is summarized as Technology No. 4b in Table 5-1.

Screening Result

Tilling is being retained for comparison with other remedial technologies in the FS and for potential use in conjunction with other technologies where implementability may be low. Tilling could potentially be applied at the majority of the site areas containing sufficient equipment access and appropriate terrain slopes or at targeted locations where it is determined that lime and organic matter soil amendments are not warranted.

5.1.7 Soil Amendments – Ferrihydrite

The use of the soil amendment ferrihydrite as a potential soil remedial technology is being evaluated for use at STSIU as part of a comprehensive remedial alternative. The addition of ferrihydrite to soils containing copper has been observed to bind copper, reduce free Cu^{2+} activity, and total soluble and labile concentrations of copper. The soil amendments - ferrihydrite technology is summarized as Technology No. 4c in Table 5-1.

Screening Result

A site-specific data gap for this particular technology currently exists. And if this technology were to be considered a pilot and/or bench-scale treatability study would be proposed. However, pilot and/or bench scale treatability studies are not being proposed to be conducted at this time. This technology is not being retained for remedial alternatives evaluation in Section 6.

5.1.8 Soil Amendments – Chelating Agents

The application of chelating agents as a potential soil remedial technology is being evaluated for use at STSIU as part of a comprehensive remedial alternative. Specifically, chelating agents are being evaluated for use in the following soil remedial technologies:

- Phytoextraction;
- Soil Washing (Ex-Situ); and
- Soil Washing (In-Situ).

Chelating agents are compounds that are added to the soil to either assist in increasing the uptake of the contaminant (i.e., copper) into plants for the phytoextraction process or for removing a metal from soils as part of a soil washing technique. The use of chelating agents in the phytoextraction and soil washing processes are discussed in detail below and are summarized as Technologies Nos. 4d1, 4d2, and 4d3 in Table 5-1.

5.1.8.1 Soil Washing (Ex-Situ)

Ex-situ soil washing is a soil remedial technique consisting of removing and concentrating contaminants from bulk soil using separation methodologies. Soil washing can be applied to soils containing heavy metals. The resulting concentrated soil containing the contaminants must be characterized for further treatment and/or offsite disposition. The “clean” portion of the separated soil is also characterized to determine if it meets the criteria for on-site reuse to be returned to the excavations or if it requires further treatment and/or offsite disposition.

The design of the soil washing process, including the size of scrubber unit, type of soil washing detergent, and soil handling requirements, will be determined via a pilot treatability study and during the remedial design.

Screening Result

Although the cost of soil washing may be moderately lower than excavation, the uncertainty of this technology and the access limitations of water and equipment to certain areas of the STSIU does not make it a viable remedial technology. Soil washing is not being retained as a remedial technology for consideration as part of the comprehensive remedial alternative for further evaluation in the FS Report.

5.1.8.2 Soil Washing (In-Situ)

In-situ soil washing consists of introducing a chelating agent into the soil. The chelating agent assists in mobilizing the contaminant within the soil column and allows it to become more soluble in the groundwater. The groundwater, containing the site contaminant, is then extracted with a groundwater extraction system for treatment and/or disposal.

Screening Result

Due to the lack of infrastructure required for the groundwater extraction system, the high costs, and the uncertainty in the effectiveness, in-situ soil washing is not considered a viable remedial technology. In addition, site accessibility issues, including the remoteness of the site and incongruous nature of areas needing treatment, will make soil washing less implementable or potentially infeasible for certain portions of STSIU. Therefore, in-situ soil washing is not being retained as a remedial technology for consideration as part of the comprehensive remedial alternative for further evaluation in the FS Report.

5.1.8.3 Phytoextraction

Phytoextraction is the process of plants taking up contaminants (i.e., copper) located in the soils via the plant root system. Once the metals have been transferred through the root system, the contaminants are subsequently transferred and accumulated into the aboveground portions of the plant tissue. Once the phytoaccumulation (contaminants transferred to the above ground plant tissue) has occurred, the contaminants are removed from the site by harvesting the plants. An additional phytoextraction technology consists of the contaminant accumulation occurring just in the root system, resulting in the need to harvest the entire plant (including the roots) to remove the contaminants from the site. The plant species selected for phytoextraction must be able to tolerate the site contamination (i.e., copper), must be fast growing, have a high biomass, and easily be harvested.

Screening Result

Although phytoextraction costs significantly less during the initial phase of treatment and is less invasive as compared to other soil remedial technologies, the uncertainty of this technology being effective in the natural environment, the potential of SGFBs consuming impacted vegetation and seeds, and the significantly increased treatment duration, does not make it a viable option. Phytoextraction is not being retained as a remedial technology for consideration as part of the comprehensive remedial alternative for further evaluation in the FS Report.

5.1.9 Containment – Soil Cover

The use of a soil cover is being considered as a potential remedial technology at the site to contain the impacted soils and prevent exposure of site contaminants to potential site receptors. As part of this remedial technology, a soil cover would be placed over existing soils with site contaminant levels above the Pre-FS RAC values. In addition, areas of the site that currently consist of soils intermixed with exposed bedrock but have been determined to historically contain fully established soil and vegetative covers will be considered for a soil cover.

The purpose of the soil cover is to place imported, approved soils upon impacted soils or exposed bedrock areas to provide a layer of clean soil that would provide protection of SGFBs and would promote growth of local, naturally occurring vegetation. Clean, approved soil cover material would be spread, graded, and compacted to promote positive drainage. The minimum thickness and type of soil, including percentage of organic matter, to be used for the soil cover would be selected during the remedial design. The containment – soil cover technology is summarized as Technology No. 5a in Table 5-1.

Screening Result

Installation of a soil cover is considered to be a viable, cost-effective, and easily implementable remedial technology and will be retained as a remedial technology to be considered a part of the comprehensive remedial alternative for further evaluation in the FS Report.

5.1.10 Containment – Impermeable Cover

This remedial technology consists of placing an impermeable cover over targeted areas with soil contaminant levels above the pre-FS RAC. This technology would include preparing the ground surface and site grades to accommodate the installation of the impermeable cover layer. Ground surface preparation activities would include clearing and grubbing existing vegetation and smoothing and compaction of the ground surface using general construction equipment such as excavators, graders, and rollers. Once proper ground surface conditions have been met (i.e., site grade and subgrade compaction), the impermeable cover would be installed. Details of the impermeable cover, including subgrade preparation requirements, subbase layers, and final impermeable cover material and thickness would be determined during the remedial design. The containment – impermeable cover technology is summarized as Technology No. 5b in Table 5-1.

Screening Result

Because it is not practical to implement this technology on a large scale and due to the impacts of surface water infiltration and stormwater run-off, and limitations on future vegetated growth and grazing, an impermeable cover is not considered a viable remedial technology to be retained for further evaluation in the FS Report.

5.1.11 Surface Soil Controls – Phytostabilization

The purpose of surface soil controls is to further stabilize the surface soils to prevent or greatly reduce airborne dispersion of soils and provide overall erosion control for storm water. Phytostabilization is considered a remedial technology that would provide increased surface soil controls. Phytostabilization consists of vegetating the ground surface with plant species that are targeted at increasing long term soil stabilization as compared to existing vegetative conditions and/or other revegetation options that are not focused specifically on soil stabilization. The seed and plant species, planting locations and density, thinning requirements, and OMM activities would be determined during the remedial design. The surface soil controls - phytostabilization technology is summarized as Technology No. 6 in Table 5-1.

Screening Result

Phytostabilization is not considered a standalone remedial technology that is effective at reducing site contaminants in the soils; therefore, this remedial technology will not be retained for evaluation in Section 6.

5.1.12 Phytoremediation

Phytoremediation consists of planting vegetation (trees and/or plants) that can uptake the contaminants located in the soil and subsequently remediate the soils. Trees and/or plants remove the site contaminants when the roots take in water and nutrients from the surrounding impacted soils. Metals are stored in the roots, stems, or leaves of the vegetation, effectively removing them from the soil. Activities that are associated with the implementation of phytoremediation include selection of the proper tree and plant species, site preparation (potentially clearing and grubbing existing vegetation), planting, and OMM to ensure that the trees and plants are being established. The phytoremediation technology is summarized as Technology No. 7 in Table 5-1.

Screening Result

Due to the extended time period it would initially take to reduce site contaminants from the soils and the fact that the site remedy effectiveness is directly dependent on the success of the trees and plants, phytoremediation is not being retained for further evaluation in the FS Report.

5.1.13 Electrokinetic Remediation

Electrokinetic remediation is being evaluated as part of this FS for use at the site as part of the comprehensive remedial alternative. Electrokinetics is based on the principle that when direct current (DC) is passed through contaminated soil, certain (negatively charged) types of contaminants will migrate through the soil pore water to a place where they can be removed. This alternative uses electrode assemblies that are installed in the ground in a square array and connected to a DC voltage power supply. When the DC power supply is activated, a current passes through the soil. As the electric current is applied to the soil between the electrodes, water flows by electroosmosis in the soil pores usually toward the cathode. When the contaminated water reaches the cathode, it is pumped to the surface by circulating water within the ceramic casing.

Electrokinetic remediation has the potential to provide remediation of copper contamination without physically removing any soil. The lack of physical soil removal allows for remediation without impacting the surface vegetation at the cost of increasing acidity in the surface soil. This increase in acidity would compound the already low overall pH in Chino soils east of the historic smelter. The electrokinetic technology is summarized as Technology No. 8 in Table 5-1.

Screening Result

It is assumed that it is not practical to implement this remedial technology over large-scale area, and therefore this technology will not be retained for further evaluation in the FS Report. Even on a small scale, the potential decreased soil pH and difficulties implementing this alternative in areas with low soil moisture are considered significant enough that this alternative will not be retained for evaluation in the FS Report.

5.1.14 Summary and Identification of Data Needs

The following soil remedial technologies were evaluated in the preliminary screen:

- No Action [retained];
- Monitoring [retained];
- Excavation and Reuse [retained];
- Excavation and Disposal [not retained];
- Soil Amendments – Lime and/or Organic Matter [retained];
- Soil Amendments – Tilling [retained];
- Soil Amendments – Chelating Agents [not retained];
- Soil Amendments – Ferrihydrite [not retained];
- Containment – Soil Cover [retained];
- Containment – Impermeable Cover [not retained];
- Surface Soil Controls – Phytostabilization [not retained];
- Phytoremediation [not retained]; and
- Electrokinetic Remediation [not retained].

Besides ongoing sampling activities, there are no additional data needs that need to be considered based on this preliminary screen of remedial alternatives for soil.

5.2 Surface Water

As part of the FS Proposal, a range of potential surface water remedial technologies have been identified and summarized for the drainage areas and stock tank associated with the Site. A preliminary screening and evaluation of the potential surface water remedial technologies has been performed to determine which remedial technologies should be retained for consideration as part of the FS, which will include a comprehensive alternatives evaluation for the site. The preliminary screening of each remedial technology is based on USEPA (1988) and includes an evaluation of the effectiveness, implementability, and cost.

Based on the preliminary screening, if the remedial technology is considered viable, it will be retained for consideration as part of the site-wide remedial alternatives analysis. As a result of this review, seven technologies were identified and are described in detail below and a preliminary screening of each technology in presented in Table 5-2.

5.2.1 No Action

This remedial technology consists of leaving the drainage areas which are known to contain surface water with levels of site contaminants above surface water Pre-FS RAC values, in their current condition without performing any soil, sediment, vegetation, groundwater and/or surface water removal or treatment. This technology is being retained to serve as a baseline control to compare to other potential surface water remedial technologies. This technology is summarized as Technology No. 1 in Table 5-2.

Screening Result

No Action is being retained as a baseline control for comparison with other remedial technologies in the FS and for potential use in conjunction with other technologies where implementability may be low.

5.2.2 Monitoring

This remedial technology consists of leaving the drainage areas which are known to contain surface water with levels of site contaminants above surface water Pre-FS RAC values, in their current condition without performing any soil, sediment, vegetation, groundwater and/or surface water removal or treatment. As part of this technology, a monitoring program would be implemented to observe and document the occurrence of natural attenuation of site contaminants. Monitoring would include collection of qualitative and quantitative samples of site media such as surface water, in-drainage sediments, and/or vegetation. This technology is being retained to serve as a baseline control to compare to other potential surface water remedial technologies. This technology is summarized as Technology No. 2 in Table 5-2.

Screening Result

Monitoring is being retained as a baseline control for comparison with other remedial technologies in the FS and for potential use in conjunction with other technologies where implementability may be low.

5.2.3 Excavation

This remedial technology consists of the removal of soils and/or sediments from the specified drainage areas. Based on the work conducted as part of the FS work plan, historical sediments and soils within the drainages may be contributing to surface water quality issues. Although a specific loading rate has not been determined for historical sediments for each drainage, sediments have been identified as a potential source to surface water. Therefore, excavation will be considered a viable remedial technology to consider for the comprehensive remedial alternative. This technology is summarized as Technology No. 3 in Table 5-2.

Screening Results

Excavation of sediments is an effective and technically implementable way of removing contaminated sediments from surface water although the costs associated with the excavation of sediments are considered to be high.

Therefore, excavation of sediments is being retained for further evaluation as part of a comprehensive remedial alternative in the FS.

5.2.4 In-Stream Removal of Suspended Sediments

This remedial technology consists of in-stream removal of suspended sediments via construction of settling basins within the stream drainage area pathway. The contaminants are adhered to the suspended sediments located within the surface water, subsequently contributing to the exceedances of the surface water Pre-FS RAC values. Removal of the suspended sediments containing the contaminants will result in lowering the total contaminant concentrations in the surface water. There may still be a potential for dissolution of contaminants from sediments into the dissolved phase.

Multiple settling basins would be constructed at specified locations along the drainage area to capture sediments at different points along the surface water drainage pathway. The location, size, and materials of the settling basins would be determined during the remedial design. The settling basins would be located in areas that are easily accessible by construction equipment for removal of the accumulated sediments. The frequency of sediment removal from the settling pools will depend on the rate of sediment accumulation and would be determined during the remedial design. This technology is summarized as Technology No. 4 in Table 5-2.

Screening Results

In-stream removal of sediments seems to be an effective, technically implementable, and cost-effective way of removing contaminated sediments from surface water. Therefore, in-stream removal of sediments is being retained for further evaluation as part of a comprehensive remedial alternative in the FS.

5.2.5 Limestone Treatment

This ex-situ remedial technology consists of the installation of limestone features within the surface water drainage area to passively treat surface water with contaminant levels above the Pre-FS RAC levels. Contaminants which either adhere to the suspended sediments in surface water or are within the dissolved phase contribute to lowering the pH of the water which creates a more acidic environment when compared to naturally occurring surface water in the region that do not contain the contaminants.

Limestone features would require installation at multiple locations along the surface water drainage areas. The multiple locations of the limestone features would provide increased treatment of the surface water as it progresses down the drainage area. The limestone features installation may consist of the construction of a waterfall using limestone masses to increase surface water contact of the water with the limestone. In addition, limestone may be installed as armoring and/or chips. The final design and location of the limestone features would be determined during the remedial design. This technology is summarized as Technology No. 5 in Table 5-2.

Screening Results

Limestone treatment is an effective and technically implementable way of removing contaminated sediments from the surface water. Therefore, installation of limestone features is being retained for further evaluation as part of a comprehensive remedial alternative in the FS.

5.2.6 In-Situ Treatment

This in-situ remedial technology consists of the insertion of an alkaline fluid into the active channel and bar sediments in the drainages of the STSIU to treat surface water with contaminant levels above the Pre-FS RAC levels.

In-situ treatment would need to be evaluated using a pilot study to determine the effectiveness of this technology on the STSIU sediments. This technology would only be an effective remedial technology if the majority of metals loading for the STSIU drainages are related to constituents in legacy sediments. If in-situ treatment is determined to be an effective remedial technology, however, this technology would require extensive infrastructure installation along the drainages for transport and treatment of an alkaline fluid. The final design and location of this infrastructure would be determined during the remedial design. This technology is summarized as Technology No. 6 in Table 5-2.

Screening Results

In-situ treatment may be effective and technically implementable way of neutralizing contaminated sediments prior to leaching to surface water, but due to the low implementability and high cost, this technology is not being retained for further evaluation as part of a comprehensive remedial alternative in the FS.

5.2.7 Sediment and Erosion Control

Based on the surface water quality data, presented in Section 4, stormwater run-off originating from the upland areas of the site is a contributing factor to surface water impacts within the drainage areas, a comprehensive sediment and erosion control system could be constructed to minimize impacts from entering the drainage areas. The sediment and erosion control system would be considered a permanent remedial technology that would reduce contaminants from entering the surface water located within the drainage area systems.

The sediment and erosion control system would consist of adjusting surrounding grade elevations where necessary and installing various types of BMPs to redirect upland run-off away from the surface water drainage areas and allow it to infiltrate directly into the upland soils. Grading adjustments may include, but may not be limited to, construction of swales, drainage ditches, and/or catch ponds to capture stormwater run-off for infiltration and/or redirect stormwater run-off from entering the drainage areas.

Temporary and permanent BMPs may be utilized as part of the sediment and erosion control system. Temporary BMPs may include silt fences, straw bales, and/or erosion control mats to be installed during construction and be maintained for a limited time after construction until vegetation has sufficiently been established. Permanent BMPs may include placement of gravel, stone, and/or riprap to be placed on newly graded areas, as warranted. The erosion and control system, including grading adjustments and BMP details would be determined during the remedial design. This technology is summarized as Technology No. 7 in Table 5-2.

Screening Results

Construction of sediment and erosion control systems near the drainage areas are considered to be effective, technically implementable, and cost effective. Therefore, installation of sediment and erosion control systems is being retained for further evaluation as part of a comprehensive remedial alternative in the FS.

5.2.8 Summary and Identification of Data Needs

The following surface water remedial technologies were evaluated in the preliminary screen:

- No Action [retained];
- Monitoring [retained];
- Excavation [retained];
- In-stream Removal of Suspended Sediments [retained];

- Limestone Treatment [retained];
- In-situ Treatment [not retained]; and
- Sediment and Erosion Control [retained].

Besides ongoing sampling activities, there are no additional data needs that need to be considered based on this preliminary screen of remedial alternatives for surface water.

A summary of retained remedial technologies is included in Table 5-3.

6. Assembly and Development of Remediation Alternatives

In this Section, remediation technologies retained after screening in Section 5 are assembled into remediation alternatives to identify one or more options that will address the remedial action objectives. A summary of the remediation technologies and alternatives are presented in Tables 6-1 through 6-4. A more detailed description of the technologies is presented in Section 5.

6.1 Soils Alternatives – Total Metals

Five alternatives have been developed to consider for remediation of the soils for total metals within the STSIU. The regulatory standards for human health and ecological risk are different. Human health standards are 5,000 mg/kg of copper and 100,000 mg/kg for iron. Avian risk is based on 95UCL area-weighted average concentration within an exposure unit with concentrations greater than 1,600 mg/kg with concentrations greater than 1,100 mg/kg requiring monitoring. The alternatives are summarized in Table 6-1. A summary of the areas is presented in Figure 6-1.

- Alternative 1: No Action
- Alternative 2: Monitoring
- Alternative 3: Select Excavation and Monitoring
- Alternative 4: Containment – Soil Cover
- Alternative 5: Soil Amendments

6.1.1 Alternative 1: No Action

A no action alternative is included as a baseline comparison to the other remedial alternatives. This alternative would leave the site for upland soil for arsenic, lead and copper in its current state.

6.1.2 Alternative 2: Monitoring

In this alternative monitoring of upland soils would be monitoring for potential natural attenuation of copper concentrations in areas that fail the human health or ecological Pre-FS RAC including 95UCL area-weighted average copper concentrations within exposure units with concentrations greater than 1,100 mg/kg for avian risk.

6.1.3 Alternative 3: Select Excavation and Monitoring

In this alternative, excavation is a technology that can reduce soil copper concentrations greater than 5,000 mg/kg for human health and 1,600 mg/kg for avian risk. Monitoring of 95UCL area-weighted average concentration within an exposure unit with concentrations between 1,100 and 1,600 mg/kg of copper would be conducted for avian risk. NMED (2011) indicates,

> *Chino shall propose risk-based monitoring of abiotic and/or biotic media to help ensure that risk from copper exposure of small ground-feeding birds in the exposure unit do not exceed acceptable levels. A protectiveness assessment consistent with CERCLA guidance will be conducted on a population basis…This monitoring shall include, at a minimum, ground-dwelling invertebrates, an indicator of copper exposure to birds that feed primarily on invertebrates during*

> *critical life stage. This requirement is intended to offset uncertainties in estimated copper exposure between 1,100 and 1,600 mg/kg. Monitoring shall be conducted in intervals no greater than 2 years for the first 5 years to establish a trend within the first 5 year review period. Monitoring frequency beyond the first years will be determined based on the first 5 year review recommendations.*

Monitoring would be completed once NMED issues the ROD. Excavated soil, greater than the RAO, would be excavated and taken to the operational area for subsequent reuse.

6.1.4 Alternative 4: Containment and Monitoring

This alternative is a combination of soil cover long-term maintenance and monitoring. It would be implemented for the same area as Alternative 3, by covering all areas for human health (5,000 mg/kg) and avian risk (1,600 mg/kg). This alternative would include the placement of a clean cover (minimum 6-inches of soil) over the exposure areas and revegetation. Long-term maintenance and monitoring of the cover would be required, and institutional controls would be required.

6.1.5 Alternative 5: Soil Amendments and Monitoring

This alternative is a combination of soil amendments, with potentially tilling implemented for the same areas as Alternative 3 and 4. This alternative would implement soil amendments based on the results of the soil amendment study, with the option for tilling the soil amendments into the 6-inch depth of the surface soils. The soil amendment study is a completed five year study, and the last year of the study was in 2013. Details of the soil amendment design are based on the final results of the soil amendment study.

6.2 Soils Alternatives – Cupric ion activity

Six alternatives have been developed to consider for remediation of the soils for pCu within the STSIU. The areas being considered for remedial alternatives are the areas presented in Figure 3-12 that have pCu concentrations equal to or less than 4.6, where copper concentrations are greater than 327 mg/kg, and also meet the evaluation criteria described in Section 3.2.4. There is some overlap between the areas discussed in Section 6.1 (total metals) and Section 6.2 (pCu) (Figure 6-1). The selection of a remedy for each remedial component may have an impact on the other. This interaction will be described in Section 7. The alternatives are summarized in Table 6-2.

- Alternative 1: No Action
- Alternative 2: Monitoring
- Alternative 3: Excavation and Monitoring
- Alternative 4: Tilling and Monitoring
- Alternative 5: Soil Amendments/Tilling
- Alternative 6: Partial Excavation and Soil Amendments/Tilling

6.2.1 Alternative 1: No Action

A no action alternative is included as a baseline comparison to the other remedial alternatives. This alternative would leave the site for upland soil for pCu in its current state.

6.2.2 Alternative 2: Monitoring

In this alternative, upland soils for pCu would be monitored for potential natural attenuation of copper concentrations in areas that have a pCu less than 4.6, where copper concentrations are greater than 327 mg/kg.

6.2.3 Alternative 3: Excavation and Monitoring

In this alternative, to the extent possible, low pCu areas would be excavated until the pCu of the top six inches of soil meet the criteria of greater than 4.6 or copper drops below 327 mg/kg. Excavated soil, greater than the RAO, would be taken to the operational area for subsequent recycling. Excavation of low pCu soils would be limited because of the infeasibility for completions in areas of bedrock and steep slopes.

6.2.4 Alternative 4: Tilling and Monitoring

In this alternative, to the extent possible, low pCu areas would be tilled using mechanical means. No soil amendments or addition of organic material would be included in this alternative. Tilling would not be conducted on areas inaccessible to the mechanical equipment, on bedrock outcrops. Monitoring of the areas would be conducted to determine if the pCu values are stable over time.

6.2.5 Alternative 5: Soil Amendments, Tilling, and Monitoring

Based on the results of the soil amendment study plots, a recipe for soil amendments (e.g. lime but not organic material) would be added to areas where pCu is less than 4.6. This alternative is Alternative 4 with the addition of amendments in areas where soils cannot be tilled (e.g., too shallow or steep slopes). This alternative may be appropriate as it provides additionally for amendments in areas where tilling is not feasible. However, some areas may still be inaccessible, even on foot, for application of amendments.

6.2.6 Alternative 5: Partial Excavation, Soil Amendments, Tilling, and Monitoring

This alternative is a combination of Alternative 3, 4 and 5 and targets the use of each of the alternatives to the areas that are most suitable for their use. Excavation of low pCu values would be targeted in easy to reach, flatter areas that lend themselves more easily to use of heavy equipment. Excavation would be targeted to the areas around the former smelter location and immediately to the east. Soil amendments and/or tilling would target areas that have either bedrock outcrops in them or are located further away from the former smelter.

6.3 Surface Water Alternatives – Drainages

Five alternatives have been developed to consider for remediation of the surface water drainages within the STSIU. The drainages being evaluated for remedial alternatives are the yellow drainages on Figure 6-1 that have water quality concentrations higher than water quality standards and have the potential for exposure to a receptor. Alternatives to address both drainage surface water run-off and drainage sediments. A more detailed description of the technologies is described in section 5. The alternatives are summarized in Table 6-3.

- Alternative 1: No Action
- Alternative 2: Monitoring
- Alternative 3: Select Excavation and Monitoring

- Alternative 4 Select Excavation, Sediment Control, Limestone Treatment, and Monitoring
- Alternative 5: Sediment Control, Erosion Control, and Monitoring

6.3.1 Alternative 1: No Action

A no action alternative is included as a baseline comparison to the other remedial alternatives. This alternative would leave the site the way it is for surface water drainages.

6.3.2 Alternative 2: Monitoring

In this alternative surface water drainages would be monitored for natural attenuation for copper against surface water quality parameters.

6.3.3 Alternative 3: Excavation and Monitoring

This alternative would excavate deposited historical sediments from potential aquatic habit pools, and upstream of the pools to the extent that the drainages are accessible, in selected or targeted areas along each of the yellow drainages identified in Figure 6-1 (i.e., hot spot removals or receptor locations). Excavation would be conducted only in the drainages and would not extend to the upland soils, as upland soils are addressed in the remedies discussed previously. Long-term monitoring of the surface water quality would be conducted in each of the drainages to document that the surface water quality is improving. This alternative would address historical sediments within the surface water drainages but would have limited impact on new sediments generated from upland soils.

6.3.4 Alternative 4: Excavation, Sediment Control, Limestone Treatment, and Monitoring

In this alternative sedimentation basins would be constructed within the yellow surface water drainages, as shown on Figure 6-1. The sedimentation basins would be constructed of limestone rock and slabs to increase the pH of surface water; thereby decreasing the bioavailability of copper in surface water. Construction of the sedimentation basins within existing areas of lower velocity would also provide an opportunity to excavate existing sediments within the surface water drainages and replace the material with limestone, thereby reducing total copper concentration of in-channel sediments. This alternative would address both the transportation of total copper, as well as dissolved copper concentrations. Long-term monitoring of the surface water quality would be conducted in each of the drainages to document that surface water quality is improving.

6.3.5 Alternative 5: Sediment Control, Erosion Control, and Monitoring

In this alternative BMPs and slope changes would be made to prevent the movement of suspended sediments from entering surface water drainages. This alternative would be most appropriate for areas where upland treatments or removals are not conducted. BMPs would be installed along select locations along the length of the yellow surface water drainages in Figure 6-1. Targeted stream length would be in areas with the highest potential for sediment loading. This alternative would address suspended sediment contribution to total copper concentrations and potential loading of sediments to the surface water drainages. This alternative would require long-term monitoring of surface water quality to determine if it is improving as well as monitoring and maintenance of the constructed/ installed BMPs. Preference should be given to BMPs or controls that include a limestone component which may address the dissolved phase of metals in storm water.

6.4 Surface Water Alternatives – Stock Tanks

Five alternatives have been developed to consider for remediation of the surface-water fed, earthen stock tank 6 within the STSIU. The remedial alternative for the stock tank is linked to the remedial alternatives selected for surface water drainages, discussed in Section 6.3. The alternatives are summarized in Table 6-4.

- Alternative 1: No Action
- Alternative 2: Monitoring
- Alternative 3: Excavation and Monitoring
- Alternative 4: Excavation, Limestone and Monitoring

6.4.1 Alternative 1: No Action

A no action alternative is included as a baseline comparison to the other remedial alternatives. This alternative would leave the site for surface water drainages.

6.4.2 Alternative 2: Monitoring

In this alternative monitoring of the surface water stock tank would be conducted for surface water quality parameters and potential natural attenuation.

6.4.3 Alternative 3: Excavation and Monitoring

In this alternative the stock tank would be excavated to remove the historical sediment from the bottom of the tank. Excavated soil would be excavated and taken to the operation area for subsequent reuse. Monitoring of the stock tank would be required to document that the water quality in the stock tank meets regulatory standards.

6.4.4 Alternative 4: Excavation, Limestone, and Monitoring

In this alternative the stock tank would be excavated to remove the historical sediment from the bottom of the tank. Limestone riprap or blocks would be placed at the bottom of the stock tank to address the bioavailability of potential historical sediments and potential new sediments entering the stock tank that may not have been captured in the remedial alternatives for the surface water drainages. Concentrations of Cu in stock tank sediment are not known to be bioavailable or source to surface water and there is no Pre-FS RAC. Excavated sediment would be excavated and taken to the operation area for subsequent recycling. Monitoring of the stock tank would be required to document that the water quality in the stock tanks meets regulatory standards.

7. Analysis of Alternatives

The remediation alternatives developed in Section 6 are evaluated in this Section. A final remediation alternative is recommended for each remedial component (soils – total metals, soils – pCu, surface water drainages and a surface water stock tank).

The descriptions provided below include the major activities for each remedy at sufficient level of detail for the purposes of this FS. Detailed designs, sampling and analysis plans, inspection and monitoring plans, and other documents necessary for implementing the alternatives will be prepared at a later date after the remedy has been selected and documented in the ROD. Remedial alternative analysis based on the full list of EPA evaluation criteria, including:

- overall protection of human health and the environment;
- compliance with ARARs;
- long-term effectiveness and permanence;
- reduction of toxicity, mobility, or volume;
- short-term effectiveness;
- implementability;
- cost-effectiveness;
- NMED acceptance; and
- community acceptance.

In addition to the above standard EPA evaluation criteria, the remedial alternatives will be evaluated using green remediation criteria. Factors for each remedial alternative that will be evaluated will also be evaluated as a green alternative, which may include, but may not be limited to, conservation of natural resources, carbon footprint, greenhouse gas emissions, and sustainability of the design.

The first two criteria are considered threshold criteria. Threshold criteria are minimum requirements that much we satisfied by an alternative. These criteria are applied to individual alternatives, but not used in the comparative evaluation of alternatives. The next five are the balancing criteria. Comparative evaluation is based on the balancing criteria used to assess tradeoffs between each alternative.

The remaining two criteria, state and community acceptance are modifying criteria and are more difficult to assess at the FS stage. Typically, after the FS is finalized an alternative is selected as the proposed remedial action. The proposed remedial action is described along with the basis for its selection in the Proposed Plan. The evaluation of the modifying criteria is based on the state and public comments on the FS and the Proposed Plan. State and community concerns, and any resulting changes in the selected remedial actions, are documented in the ROD for the site. Therefore, the two modifying criteria are not evaluated in this document.

Each of the remedial alternatives have been summarized in Table 7-1 through 7-4 for: soils – total metals, soils – pCu, surface water drainages, and surface water stock tanks. A summary of the areas, length and stock tanks is presented below. Although evaluated separately in Section 6.1 and 6.2 and presented in Section 7.2 and 7.3, the selection of a remedial alternative for the upland soils will focus on the 113 acres of flat-rocky soils presented in

Figure 3-14 and the selection of a remedial alternative for surface water will focus on the C and D3 Drainages in addition to stock tank 06.

7.1 Evaluation Criteria

7.1.1 Threshold Criteria

Under CERCLA, remediation alternatives must meet the following two threshold requirements:

- overall protection of human health and the environment;
- compliance with ARARs;

7.1.1.1 Protection of Human Health and Environment

This criterion addresses the degree to which the alternative is protective of human health and the environment, considering both long-term and short-term risks. Overall protectiveness is a threshold criterion, in those alternatives that does not achieve adequate protection of human health or the environment are eliminated from further consideration. The ability of the alternatives to achieve remedial action objectives is part of the evaluation of this criterion. This criterion considers the evaluation of other criterion, especially long-term effectiveness and permanence; reduction of toxicity, mobility and volume; and short-term effectiveness. This is a summary of the overall evaluation of these other criterion. Because of the overall, it is evaluated for screening individual alternatives, but not used in comparative evaluation of the alternatives.

7.1.1.2 Compliance with ARARs

This criterion addresses whether or not the alternative meets ARARs, which were defined in Section 2. As with overall protectiveness, compliance with ARA is a threshold criterion that much be met for an alternative to be selected.

7.1.2 Balancing Criteria

7.1.2.1 Long-term Effectiveness and Permanence

This criterion addresses the results of remedial actions in terms of the risk remaining at the site after the response action objectives have been met and the reliability of the remedial action at reducing risks over an extended period of time. The primary focus of this evaluation is the extent and effectiveness of the control that may be required to manage the risks posed by the contaminants in the long-term.

7.1.2.2 Reduction of Toxicity, Mobility, or Volume through Treatment

This criterion addresses the degree to which a remediation alternative reduces the toxicity of contaminants, the ability of the contaminants to migrate into the accessible environment, or the volume/quantity of the contaminated material. This criterion focuses the analysis of the preference for treatment under CERCLA. Effectiveness and reliability of treatment are addressed under long-term effectiveness and permanence, and are not addressed under this criterion.

7.1.2.3 Short-term Effectiveness

This criterion addresses short-term effects on human health and the environment while the alternative is being implemented. The following factors should be addressed as appropriate for each alternative: protection of community and workers during construction, environmental impacts, amount of time to implement the remedial actions.

7.1.2.4 Implementability

This criterion addresses the degree of difficulty in implementing each alternative. Implementability can be divided into three categories: technical feasibility, administrative feasibility, and availability of services and materials. Implementability is a key criterion for more complex alternatives and reliance on innovative technology increases. Implementability issues are important because they address the potential for schedule delays, costs increases, and remedy failure to achieve the intended results. The evaluation considers the following:

- *Technical Feasibility.* Addresses site-specific factors that could prevent successful implementation of an alternative. As previously mentioned in Section 5 implementability issues could include physical interferences, such as bedrock, steep slopes or limited access.
- *Administrative Feasibility.* The degree of difficulty anticipated due to regulatory constraints such as permit approvals and degree of coordination between regulatory agencies and stakeholders.
- *Availability of Services and Materials*. The availability of labor, equipment and materials to implement the alternatives.

7.1.2.5 Cost

The criterion is used to consider the costs of implementing each alternative including capital costs and operating, monitoring, and maintenance costs. Costs that are excessive compared to the overall effectiveness may be considered as one of several factors used to eliminate an alternative. Alternatives providing effectiveness and implementability similar to that of another alternative, but at a higher cost, may be eliminated.

7.1.3 State and Community Acceptance

The last two evaluation criteria are not evaluated in the STSIU FS. These criteria will be addressed in the ROD.

7.1.4 Green Remediation

Factors for each remedial alternative that will be evaluated will also be evaluated as a green alternative, which may include, but may not be limited to, conservation of natural resources (fuel), carbon footprint, greenhouse gas emissions, and sustainability of the design.

7.2 Evaluation of Soils Alternatives – Total Metals

As presented in Section 3, all sample-specific concentrations were less than the 5,000 mg/kg Cu and 100,000 mg/kg Fe Pre-FS RAC for human health unless removal could not be accomplished due to bedrock, infrastructure or steep slope. All habitat alliance polygons had a 95 UCL area-weighted average Cu concentration less than 1,600 mg/kg for avian. Three polygons had 95UCL area-weighted average Cu concentrations between 1,100 and 1,600 mg/kg (1-3, 10-16 and 88-15). It is therefore appropriate to evaluate remedial alternatives for these acres.

The alternatives are summarized as:

- Alternative 1: No Action
- Alternative 2: Monitoring

- Alternative 3: Excavation and Monitoring
- Alternative 4: Containment and Monitoring
- Alternative 5: Soil Amendments and Monitoring

Only Alternatives 1 and 2 are evaluated because there are 140 acres identified with 95UCL area-weighted average concentrations between 1,100 - 1,600 mg/kg. For these acres, Alternative 1 does not meet the threshold criteria because the acres do not meet the Pre-FS RAC for monitoring pCu and, therefore, do not meet the state's criteria. Alternative 2 is monitoring and this remedial alternative meets the state's Pre-FS RAC. Alternative 2 is also considered the greenest remediation alternative behind Alternative 1. Based on the amendment, pH and insect studies, the white rain in 2008 reduced copper uptake into plants and thus reduced phytotoxicity, and improved plant richness. However, NMED (2011) indicates that:

> *If the 95UCL area-weighted average copper concentration in an exposure unit exceeds 1,100 mg/kg, Chino shall propose risk-based monitoring of abiotic and/or biotic media to help ensure that risk from copper exposure of small ground-feeding birds in the exposure unit do not exceed acceptable levels. A protectiveness assessment consistent with CERCLA guidance will be conducted on a population basis. This requirement is intended to offset the uncertainty in risk conclusions for this area due to the paucity of soil and invertebrate data available to characterize risk since the cessation of smelter operations and the 'white rain' event of January 2008. This monitoring shall include, at a minimum, ground-dwelling invertebrates, an indicator of copper exposure to birds that feed primarily on invertebrates during critical life stage. This requirement is intended to offset uncertainties in estimated copper exposure between 1,100 and 1,600 mg/kg. Monitoring shall be conducted in intervals no greater than 2 years for the first 5 years to establish a trend within the first 5 year review period. Monitoring frequency beyond the first years will be determined based on the first 5 year review recommendations.*

A monitoring work plan will be submitted as part of the basis of design after the ROD is issued. Total estimated cost is $1.3MM.

7.3 Evaluation of Soils Alternatives – pCu

As described in Section 3, nearly 4,000 acres of upland have been remediated or reclaimed including interim actions and soil removals under reclamation. For all remaining acres, all soil types had mean pCu concentrations less than their respective PEL except the rocky flat soil type. The acres associated with retained rangeland polygons in flat rocky soils with average pCu ≤ 4.6, which is the flat rocky PEL, totalled 113 (Figure 3-12). These acres were evaluated across the six remedial alternatives for the threshold and balancing criteria.

As discussed in Section 6, the remedial alternatives are:

- Alternative 1: No Action
- Alternative 2: Monitoring
- Alternative 3: Excavation and Monitoring
- Alternative 4: Tilling and Monitoring
- Alternative 5: Soil Amendments, Tilling, and Monitoring
- Alternative 6: Partial Excavation, Soil Amendments, Tilling, and Monitoring

Although Alternatives 1 and 2 are the greenest of the remediation alternatives considered, they do not meet the threshold criteria because the acres do not meet the Pre-FS RAC for pCu and, therefore, do not meet the state's criteria for reduction of risk to vegetation. The ability of Alternative 2 to satisfy the criteria of "overall protection" is low; however, due to the presence of naturally occurring calcium carbonate, natural attenuation may be occurring at the site. The rate of natural attenuation is currently unknown but was enhanced by the 2008 white rain. The long-term effectiveness of this remedial alternative is dependent on natural attenuation in the future; however, a natural attenuation factor for the remediation of pCu has not be determined at this point. Based on the amendment, pH and insect studies, the white rain in 2008 decreased cupric ion activity (increased pCu), reduced copper uptake into plants and thus reduced phytotoxicity, and improved plant richness. Improvements to pCu soils beyond the improvement in 2008 from the white rain, however, are not anticipated in the short-term to meet RAO. Total estimated cost is $1.7MM.

Alternative 3, which is a moderately green remediation alternative, is removal and monitoring of low pCu soils. This alternative would meet overall protection for ecological receptors; however, excavation physically destroys habitat which must be restored (Redente 2004). The effectiveness of this remedial alternative in the long-term is high to increase pCu values. Once excavation of historically deposited soils are removed, the source of the material would be removed; however, short term monitoring and sampling may be required to document that the excavation was sufficient. This alternative reduces toxicity, mobility, and volume of the concentration of pCu in surface soil, and this alternative is considered effective in the short-term. The implementability of this alternative is considered moderate compared to other alternatives. Total estimated cost is $5.5MM.

Alternative 4, which is also a moderately green remediation alternative, is tilling and monitoring of low pCu soils. This alternative would meet overall protection for vegetation. The ability of Alternative 4 to satisfy the criteria of "overall protection" is moderate. Natural attenuation rates for pCu have not been calculated, but tilling would increase the rate of natural attenuation compared to monitoring only. The long-term effectiveness of this alternative is considered moderate to increase pCu values. This alternative would increase the amount of volume, by mixing the topsoil layers with underlying soils, and mobility and toxicity may be reduced. Implementability is better than Alternative 3 because less equipment and movement of soil are required. Total estimated cost is $2.6MM which is half the cost of Alternative 3.

Alternative 5 is amendments, tilling, and monitoring of low pCu soils and this alternative would meet overall protection for vegetation. Amendments include lime but not organic matter. The long-term effectiveness of this alternative is considered moderate to high to increase pCu values. While lime (calcium carbonate) has been shown to increase pCu values at the site, Arcadis (2017) indicates that liming is recommended for soils with pH < 2 but liming is not that helpful above that pH, and soils pH identified herein are not less than pH 2. Organic matter was not recommended after the amendment study was completed because cow manure brought in weedy plants that degraded the habitat; however, other forms of organic matter could be considered. This alternative would be considered moderately effective in the short-term as it may take several years for the soil amendments to increase the pCu values. The implementability of soil amendments is considered high compared to the other alternatives; however, additional applications may be required if steep slopes are encountered. This alternative is not considered a green remediation alternative because of the resource and fuel use required for implementation. Total estimated cost is $3.3MM.

Alternative 6 is partial excavation, soil amendments, tilling, and monitoring of low pCu soils and this alternative would meet overall protection for vegetation. The overall protection of this alternative would be high as it is the most comprehensive and employs all the feasible technologies. The long-term effectiveness for this alternative is considered to be high, compared to the other alternatives. It reduces toxicity, mobility, and volume of the concentration of cupric ion activity (increasing pCu) in surface soil from excavated areas. Soil amendment areas with lime in very low pH soils would reduce toxicity and potentially mobility of remaining soils. Tilling would increase the volume of material but would decrease the mobility and toxicity. This alternative would be considered moderately effective in the short-term. The implementability of this alternative is considered the highest amongst all the alternatives for pCu. Because of the resource and fuel use required for implementation, this alternative is considered the least green of those considered. Total estimated cost is $4.3MM which slightly less than Alternative 3.

The recommended remedial alternative is tilling and monitoring of low pCu soils. Alternative 4 uses the natural alkalinity of the Gila Conglomerate to restore low pCu soils with the least amount of intrusiveness, lower disruption to habitat, and lower carbon footprint compared to alternatives relying on excavation. Tilling would increase the rate of natural attenuation compared to monitoring only. Implementability is better than Alternative 3 because less equipment and movement of soil are required. Total estimated cost is $2.6MM, which is a third the cost of Alternative 3.

7.4 Evaluation of Surface Water Alternatives – Surface Water Drainages

As presented in Section 4, four drainages were determined to have concentrations of potential concern to aquatic life uses, include Drainage A, Drainages C1 and C2, and Drainage D3. It is therefore appropriate to evaluate remedial alternatives for these four drainages.

Drainage A

The surface water in Drainage A is ephemeral and it is thus appropriate to use the WER-based Acute HQ when evaluating surface water quality. As included on Table 4-5, surface water results for copper were just above an HQ of 1 in 2010. Further, HQs in samples collected from stock tank 60 have historically been less than 3, HQs in samples collected from stock tanks 15 and 26 have historically been less than 2, HQs in samples collected from stock tanks 16 and 25 have been less than 1 (Table 4-7). Stock tanks 15, 26, and 60 were removed as part of rangeland improvements completed between 2013 and 2022 (see Section 4.1.2), so current data for these tanks are unavailable. However, a water quality sample was collected from stock tank 16 in 2021 and the WER-based Acute HQ for copper was less than 1. As a result of the relatively low HQs historically measured in this drainage, and because the latest sample indicates the copper HQ is less than 1, the monitoring remedy (Alternative 2) included on Table 7-3 is the most appropriate remedy for this drainage. Alternative 2 is also the greenest remediation alternative for Drainage A behind no action.

Drainages C1 and C2

The surface water in Drainages C1 and C2 are ephemeral, and it is thus appropriate to use the WER-based Acute HQ when evaluating surface water quality in these drainages. As included on Table 4-5, surface water results for copper were just above an HQ of 2 in Drainage C2 and just below an HQ of 2 in Drainage C1. Because the copper HQs are around 2 or below in these two drainages, and because more aggressive remedies may involve damaging existing vegetation that is currently thriving in these drainage systems, the monitoring remedy (Alternative 2) included on Table 7-3 is the most appropriate remedy for these drainages. Alternative 2 is also the greenest remediation alternative for Drainages C1 and C2 behind no action.

Drainage D3

The surface water in Drainages D3 is ephemeral and it is thus appropriate to use the WER-based Acute HQ when evaluating surface water quality in this drainage. As described in Section 4, two surface water drainage locations in the STSIU exceed the WER-based Acute HQ for copper in the D-3 Drainage (see Section 4.2.1). The HQs for both these exceedances were approximately 8.8 (Table 4-5). The water quality results in this drainage support one of the active remedies included in Table 7-3. However, Drainage D3 is steep, heavily vegetated, and little access is available to implement an active remedy. A road would need to be constructed to access the upgradient portions of the drainage to implement remedies involving sediment control or excavation, and the steep walls confining the drainage and heavy vegetation make this technically impractical. As a result, the monitoring remedy (Alternative 2) included on Table 7-3 is the most appropriate remedy for this drainage. Alternative 2 is also the greenest remediation alternative for Drainage D3 behind no action.

The total estimated cost for implementing a monitoring remedy for Drainages A, C1, C2, and D3 is $600K.

7.5 Evaluation of Surface Water Alternatives – Stock Tanks

As presented in Section 4, stock tank 06 was determined to have concentrations of potential concern to aquatic life uses and it is thus appropriate to evaluate remedial alternatives for this tank. The WER-adjusted acute HQ for copper has been less than 2.5 since 2006 (Table 4-7). Additionally, the approximately 230-acre drainage basin feeding stock tank 06 is currently being improved to provide for stable stormwater conveyance to the tank inlet (see Section 4.1.2). Because of these improvements, it is expected that water quality will improve in stock tank 06 with time. As a result, the monitoring remedy (Alternative 2) included on Table 7-4 is the most appropriate remedy for this stock tank. Alternative 2 is also the greenest remediation alternative of those considered for stock tank 06 behind no action. Total estimated cost is $140K.

Regulatory Program/Authority	Citation	Medium of Potential Interest	Notes
Safe Drinking Water Act (SDWA), Federal	40 CFR 141 Subpart F	Groundwater, Surface Water	Establishes primary drinking standards for public water systems.
SDWA, Federal	40 CFR 143, Subpart B	Groundwater, Surface Water	Establishes secondary non-enforceable health goals for public water systems at levels resulting in no known or anticipated adverse health effects.
Clean Air Act, Federal	40 CFR 50	Air	Establishes primary and secondary ambient air quality standards.
Clean Air Act, Federal	40 CFR 60	Air	Establishes (referenced by NMED AQCR 652) performance standards for new sources based on the specific source categories defined in the regulation.
Air Quality Control Act, State	20.2.3 NMAC	Air	Establishes ambient air quality standards.
Air Quality Control Act, State	20.2.78 NMAC	Air	Defines emissions standards for hazardous air pollutants.
New Mexico Water Quality Act	20.6.2.7.VV NMAC	Groundwater, Surface Water	Definition of a toxic pollutant.
New Mexico Water Quality Act	20.6.2.3101 NMAC	Groundwater	Designates groundwater with total dissolved solids<=10,000 mg/L as potential source of drinking water.
New Mexico Water Quality Act	20.6.4 NMAC	Surface Water	Provides water quality standards for human contact of surface waters. Defines water quality standards for livestock watering. This statute includes an anti-degradation policy, general water quality standards, primary contact standards, and wildlife standards.
New Mexico Water Quality Act	20.6.2.3103(A) NMAC	Groundwater	Establish human health standards for groundwater quality.
New Mexico Water Quality Act	20.6.2.3103(B) NMAC	Groundwater	Establishes additional standards for domestic water supplies.
New Mexico Water Quality Act	20.6.2.3103(C) NMAC	Groundwater	Establishes groundwater quality standards for irrigation use.
Resource Conservation and Recovery Act (RCRA), Federal	40 CFR 261.24	Soil	Regulates the determination of hazardous wastes by defining the maximum concentrations of listed contaminants as measured using the Toxicity Characteristic Leaching Procedure (TCLP).
CERCLA	40 CFR 300 Title 1, Section 101, 111	All Media	References the National Oil and Hazardous Substances Contingency Plan. Establishes funding and provisions for cleanup at hazardous waste sites.

Regulatory Program/Authority	Citation	Medium of Potential Interest	Description
CERCLA	40 CFR 300 Title 1, Section 101, 111	All Media	References the National Oil and Hazardous Substances Contingency Plan. Establishes funding and provisions for cleanup at hazardous waste sites.
SARA	42 USC 9601	All Media	Establishes clean-up standards and response actions, including the ARAR process (i.e. Applicable Standards).
Clean Water Act - National Pollution Discharge Elimination System (NPDES)	40 CFR 122 40 CFR 125	Surface Water	Requires permits for discharging pollutants from any point source into waters, lists hazardous substances and water-quality parameters, and defines the criteria and standards for issuances of permits, determining compliance, and granting variances. Establishes Best Management Practices (BMPs) to prevent releases of toxic constituents to surface waters.
Clean Water Act	40 CFR 230 40 CFR 231 Sec 404	Surface Water	Requires permits for discharging dredged or fill materials into the navigable waters, including wetlands or floodplains. Permits (Sec 404) are issued if the state has authorization, otherwise, Nation Wide Permits (NWPs) can be issued by the US Army, Corps of Engineers. Applies to all stream modifications, including underground and surface mining activities.
Rivers and Harbors Act of 1899	33 CFR 320 33 CFR 330	Surface Water	Regulates disposal/discharge of dredged or fill materials into US waters, including intermittent streams.
RCRA	40 CFR 241	Soil	Specifies performance requirements for land disposal of wastes.
RCRA	40 CFR 261	Soil	Defines criteria for identifying and classifying hazardous wastes.
RCRA	40 CFR 262	Soil	Establishes standards for generators of hazardous wastes, including requirements for waste shipment packaging, labeling, and manifests. Requirements may be applicable if remediation activities are performed at the S/TSIU and waste generated are hazardous.
RCRA	40 CFR 263	Soil	Establishes standards for transporters of hazardous wastes.
RCRA	40 CFR 264	Soil	Establishes standards for owner and operators of facilities for the treatment, storage, and disposal of hazardous wastes.

[1] PreFS RAC for copper for small ground feeding bird applies to 0-6" soil sieved to < 2 mm (2000 µm). Pre-FS RAC for human health applies to 0-1" soil sieved to < 0.25 mm (250 µm). Ratio used to convert copper concentration of 0-1" sieved at <0.25 mm soils to 0-6" sieved at < 2 mm soils is from Appendix A (median ratio of SS samples) of Arcadis (2011). Multiplied copper concentration by 0.7 if outside windblown tailings (and by 1.5 if inside windblown tailings). If unsieved, multiplied by 0.9 if outside windblown tailings and by 1.3 if inside windblown tailings. The 0.9 and 1.3 are from median ratios of unsieved 0-1" soil in 2009 lab reports (at 25 m on transect) compared to sieved 0-6" co-located soil in Drexler lab report in Appendix D for soils in and outside of windblown tailings, respectively (FID 8, 18, 20 in tailings).

[2] Data collected for ecological endpoint and was never corrected to HH values.

[3] A duplicate sample with the same Loc ID has been recorded in Golf Course Interim Removal Action, Arcadis 2009. This sample was maked as IRA.

[4] A duplicate sample with the same Loc ID has been recorded in Golf Course Interim Removal Action, Arcadis 2009. This sample was marked as HWY 180.

[5] A duplicate sample with the same Loc ID has been recorded in Golf Course Interim Removal Action, Arcadis 2009. This sample was marked as 2:1 slope.

[6] A duplicate sample with the same Loc ID has been recorded in Golf Course Interim Removal Action, Arcadis 2009. This sample was marked as Volcanic Rock.

TABLE 3-2
Sample Summary for Total Copper

STSIU Feasibility Study
Freeport-McMoRan Chino Mines Company
Vanadium, New Mexico

Location ID	Alternate ID		Year Collected	Original Soil depth	Sieving Status	Northing (State Plane)	Easting (State Plane)	Latitude	Longitude	Copper Concentration		Pre-IRA Dataset	Removed in Post-IRA Dataset
										To Compare to HH Pre-FS RAC (250 µm sieve)	For Bird Pre-FS RAC Analysis (2000 µm sieve)		

[7] A duplicate sample with the same Loc ID has been recorded in Golf Course Interim Removal Action, Arcadis 2009. This sample was marked as NMDOT.

[8] Samples with an initial bedrock designation that were included in the Thiessens analysis.

*Removed samples with the asterick are set to 327 for the Theissens analysis. All other removed samples are completely voided.

-- means no data available at the location

Notes:

mg/kg = milligram per kilogram

(a) Polygon has two samples and does not meet minimum sample count to run the bootstrap macro; therefore, the average concentration was estimated.

(b) The bootstrap macro will not accept N>200; therefore, the lowest weight samples are binned together.

Gray shading indicates Ratio > 1 and exceeds the corresponding RAC indicated in the column heading.

Notes:
mg/kg = milligram per kilogram
SU = standard unit
[1] used upland pCu equation from NewFields 2005, applied all points in table to pCu contours developed with natural neighbor method.
All samples taken from the 0-6" bgs interval or adjusted to 0-6" interval with sieving at < 2 mm (see Table E-1 in Appendix B)

TABLE 3-5
ERROR MATRICES

FREEPORT-MCMORAN CHINO MINES COMPANY
VANADIUM, NEW MEXICO
SMELTER/TAILING SOILS IU FEASIBILITY STUDY

Rangeland Condition Classification[1]

	Observed			
Classified	**Unacceptable**	**Acceptable**	**User's Accuracy**	**Error of Comission**
Unacceptable	2	0	**100%**	**0%**
Acceptable	1	5	**83%**	**17%**
Producer's Accuracy	**67%**	**100%**		
Error of Omission	**33%**	**0%**		

Overall Accuracy: **88%**

1. Based on a comparison of 2011 ground-verified OAT scores on 200-m transect that were independent of training dataset (1/4 of total dataset was not used for training) compared to majority classified rangeland class within the 200 m x 200 m area. Training dataset had 74% overall accuracy (18% error of commission), and all data produced 74% accuracy.

Vegetation Cover Classification[2]

	Observed			
Classified	**Unacceptable**	**Acceptable**	**User's Accuracy**	**Error of Comission**
Unacceptable	9	5	**64%**	**36%**
Acceptable	3	14	**82%**	**18%**
Producer's Accuracy	**75%**	**74%**		
Error of Omission	**25%**	**26%**		

Overall Accuracy: **74%**

2. Based on a comparison of 2011 ground visit assessed vegetative cover independent of process of developing the mapped rangeland polygons of cover.

Vegetation Richness Classification[3]

	Observed			
Classified	**Unacceptable**	**Acceptable**	**User's Accuracy**	**Error of Comission**
Unacceptable	16	5	**76%**	**24%**
Acceptable	4	6	**60%**	**40%**
Producer's Accuracy	**80%**	**55%**		
Error of Omission	**20%**	**45%**		

Overall Accuracy: **71%**

3. Based on a comparison of 2011 ground visit assessed vegetative richness independent of process of develping mapped rangeland polygons of richness.

Notes:

1. HQs adjusted using the WER determined in the sample's watershed, or nearest watershed. In cases where mutliple preliminary WERs were determined in a single watershed, the geometric mean of these WERs was calculated and used as a watershed-specific WER. A summary of preliminary watershed-specific WERs is provided below:

Sub-watershed B	4.717
Sub-watershed C	9.414
Sub-watershed D-1	8.661
Sub-watersged D-2	8.027
Sub-watershed G	6.406

2. HQs adjusted using the STSIU geometric mean WER (5.003) presented in Table 4-4.

TABLE 5-1
SOIL REMEDIAL TECHNOLOGIES

FREEPORT-MCMORAN CHINO MINES COMPANY
VANADIUM, NEW MEXICO
SMELTER/TAILING SOILS IU FEASIBILITY STUDY

NO.	REMEDIAL TECHNOLOGY	DESCRIPTION	PRELIMINARY SCREENING			CONCLUSION
			EFFECTIVENESS	IMPLEMENTABILITY	COST	
1	No Action	No further active response actions.	Contaminants will naturally attenuate over time. Does not provide additional mechanisms to prevent contaminant exposure to site receptors.	Is considered implementable.	There are no cost associated with no action.	Being retained for baseline comparison of remedial technologies.
2	Monitoring	No further active response actions. Monitoring will be conducted to prove the occurrence of natural remediation.	Contaminants will naturally attenuate over time. Does not provide additional mechanisms to prevent contaminant exposure to site receptors.	Is considered implementable.	Costs are associated with types of monitoring (quantitative and/or qualitative) and monitoring duration selected.	Being retained for evaluation as a part of a remedial alternative.
3	Excavation and Reuse	Excavation and onsite management includes removal of contaminated soils with heavy construction equipment and hand removal techniques. Excavated soils will be managed onsite at the waste rock stockpiles or reused in the adjacent operational areas as cover for the tailings ponds.	Is considered highly effective at reducing the presence of site contaminants.	Is considered to be generally technically implementable with the exception of certain areas of the site that are more difficult to access with equipment and personnel due to terrain conditions.	Costs include equipment use and maintenance, material handling and transport, and backfill materials and activities. Costs are considered less than Excavation and Disposal option because offsite transportation and disposal is not needed. Long term O&M costs are considered to be low.	Not being retained for remedial alternatives at this time.
3a	Excavation and Disposal	Excavation and disposal includes removal of contaminated soils with heavy construction equipment and hand removal techniques. Excavated soils will be characterized to determine final offsite disposition.	Is considered highly effective at reducing the presence of site contaminants.	Excavation is considered to be generally technically implementable with the exception of certain areas of the site that are more difficult to access with equipment and personnel due to terrain conditions. Offsite transportation is not considered to be economical to a permitted facility that could accept the soils. Therefore the offsite transportation and disposal is considered to have low implementability.	Costs include equipment use and maintenance, material handling and transport, backfill materials and activities, characterization, and offsite transportation and disposal. Long term O&M costs are considered to be low.	Not being retained for remedial alternatives at this time.
4	Soil Amendments					
4a	Limestone and Organic Matter	5-Year amendment study tested combinations of lime slurry and organic matter, and tilling applications. Plant coverage, pH, and soil chemistry were monitored.	After the white rain already improved many areas on the site, liming may not improve a plant community or reduce uptake into plants unless pH < 2. Organic matter amendments did not improve the plant community and contributed to proliferation of weeds toxic to wildlife. Plant communities on steep slopes > 13% were degraded by the amendments.	This technology has been demonstrated to be implementable via the ongoing amendment study. This technology may be less implementable at certain areas of the site that are not readily accessible by equipment.	Costs are moderate and include purchase and transport of amendments to the site, and equipment for application. Minimal soil handling is required as soils generally remain in place, minimizing transportation and disposal costs. Long term O&M costs are considered low to moderate.	Being retained for evaluation as a part of a remedial alternative.
4b	Tilling or Ripping	5-Year amendment study tested combinations of lime slurry and organic matter, and tilling applications. Plant coverage, pH, and soil chemistry were monitored. Tilling de-compacts soil and provides additional dilution of metals and has potential to raise alkaline pH conditions to more neutral pH conditions pending existing pH levels within the soil treatment area being tilled. Plant coverage, pH, and soil chemistry would be monitored post-tilling operations.	Tilling is most effective in compacted soils (e.g., flat rocky habitats). Is potentially effective at raising alkaline pH conditions and making contaminants less bioavailable to site receptors without the introduction of lime and/or organic matter, as observed on the haul road that was ripped.	This technology has been demonstrated to be implementable via the ongoing amendment study. This technology may be less implementable at certain areas of the site that are not readily accessible by equipment for tilling (i.e., areas with too steep of a slope, > 13%)	Tilling includes increased efforts and costs as compared to adding lime and organic matter without tilling. However, minimal soil handling is required as soils generally remain in place, minimizing transportation and disposal costs compared to excavation and soil cover. Long term O&M costs are considered low to moderate.	Being retained for evaluation as a part of a remedial alternative.
4c	Ferrihydrite	Ferrihydrite is mixed into the impacted soils to reduce the copper bioavailability to site receptors.	Effectiveness would be determined via conducting a pilot treatability study and potentially bench scale treatability study to determine the loading rate of ferrihydrite or if other amendments such as lime or magnesium oxide (MgO) would be beneficial in buffering the pH. Because iron is being introduced to the soils, evaluations would be conducted to verify that the iron levels are acceptable from a human health and ecological perspective.	This technology is considered to be implementable, based on the ongoing soil amendment study which has demonstrated that soil mixing is feasible. A pilot treatability study would be required to determine the most effective soil mixing technique.	Cost will depend on soil mixing technique determined and market value of the amendment materials. The overall technology is considered to have moderate costs and is comparable to the costs of the lime and OM amendments being tested as part of the Amendment Study. Long term O&M are considered low to moderate.	Not being retained for further evaluation.
4d1	Use of Chelating Agent: Soil Washing (Ex-Situ)	Ex-situ soil washing includes removal of contaminants from soil using separation methodologies, including "washing" the soils with a detergent and/or chelating agent solution. The resulting clean portions of soil can be returned to the site for reuse and the resulting wash mixture and contaminated soil fines would be characterized for final disposition.	Is potentially effective at removing copper from soil. However, level of effectiveness would have to be verified via a pilot treatability study.	A pilot treatability study would be required to determine implementability. Factors to consider to evaluate implementability include, but are not limited to, accessibility of soil washing materials (e.g., water source) and equipment to areas of remediation.	Ex-Situ soil washing is labor intensive and requires a high level of soil handling (excavation, washing, soil replacement). Requires disposal of used wash solution and potentially portions of soil. Cost savings include utilizing remediated soil for onsite reuse, reducing imported backfill required.	Not being retained for further evaluation.
4d2	Use of Chelating Agent: Soil Washing (In-Situ)	In-situ soil washing includes introducing a chelating agent into the soil. The objective of the chelating agent is to mobilize the copper within the soil column. The copper becomes soluble within the groundwater and the groundwater is subsequently extracted for treatment and/or disposal with a groundwater extraction system.	Is potentially effective at removing copper from soil. However, level of effectiveness would have to be verified via a pilot treatability study.	Due to the large areas needing remediation and lack of current infrastructure to support a groundwater extraction system, this is considered to have low implementability. However, a pilot treatability study would be required to determine implementability.	In-Situ soil washing is labor intensive and requires the introduction of the chelating agent into the soils, installation of groundwater extraction system, and extracted groundwater treatment and/or disposal. Costs for construction and future O&M activities are considered very high.	Not being retained for further evaluation.

TABLE 5-1
SOIL REMEDIAL TECHNOLOGIES

FREEPORT-MCMORAN CHINO MINES COMPANY
VANADIUM, NEW MEXICO
SMELTER/TAILING SOILS IU FEASIBILITY STUDY

NO.	REMEDIAL TECHNOLOGY	DESCRIPTION	PRELIMINARY SCREENING			CONCLUSION
			EFFECTIVENESS	IMPLEMENTABILITY	COST	
4d3	Use of Chelating Agent: Phytoextraction	Phytoextraction includes the planting of specified seeds and plants to uptake the contaminants through the root system into the plant tissue. The plants are then harvested on a regular basis to remove the contaminants from the site. A chelating agent can be applied to the soil to increase the rate of contaminant uptake into the plants.	Is potentially effective at removing copper from soil. Phytoaccumulation of contaminants in seeds and vegetation has potential to directly expose site receptors to contaminants. The effectiveness of contaminant removal is directly dependent on the success of the plants and the rate of contaminant uptake.	A pilot treatability study would be required to determine implementability. Factors to evaluate implementability include, but are not limited to, types of seeds and vegetation, harvesting and replanting schedule, chelating agent, and rate of contaminant uptake.	Initial costs are considered low to moderate and include costs of seeds/plants, chelating agent, and planting. O&M is considered high due to the long term harvesting and replanting schedule, maintenance of the plants, and disposal of the plant waste. Costs are considered moderate to high as compared to other technologies.	Not being retained for further evaluation.
5a	Soil Cover	A soil cover involves isolating impacted soils from potential site receptors. The soil cover would consist of clean soil and would be constructed over soils with copper levels above the site RAC to serve as a physical barrier between contaminated soils and site receptors. In addition, the cover could be constructed in areas of exposed bedrock to create pre-existing habitat for site receptors.	Is effective at protecting site receptors from underlying contaminants. Contaminants will remain onsite requiring ICs to restrict future intrusive activity practices. Maintenance of BMPs is considered critical to maintain the integrity and effectiveness of the soil cover.	Is considered to be generally technically implementable with the exception of certain areas of the site that are more difficult to access with equipment and personnel due to terrain conditions.	Costs are considered moderate as compared to soil excavation and the soil amendment technologies. There are higher initial costs associated with soil handling and placement of the cover. However, there are no costs associated with excavation or soil amending. O&M costs related to maintaining the cover are considered moderate.	Being retained for evaluation as a part of a remedial alternative.
5b	Impermeable Cover	An impermeable cover, such as asphalt or concrete, placed over targeted impacted soils would greatly minimize or eliminate the potential for direct contact of site receptors with impacted site soils.	An impermeable cover would be effective at reducing exposure of site receptors to impacted soils. However, an impermeable cover would eliminate the vegetative landscape, potential for future grazing, and would impact surface water infiltration and stormwater runoff patterns.	Installation of an impermeable cover is generally considered implementable with exception of areas that are too steep and/or areas with varying topography that can not be graded to conditions that could accommodate the cover.	Costs include surface preparation and grading, and installation of the impermeable cover, including base materials. Costs are considered to be moderate as compared to other soil remedial technologies. Long term O&M costs are considered low.	Not being retained for further evaluation.
6	Surface Soil Controls: Phytostabilization	Surface soil controls includes stabilizing surface soils to prevent or lower airborne dispersion of impacted soils and provide erosion control. Phytostabilization is considered a method to stabilize the surface soils through revegetation. Phytostabilization consists of revegetating the impacted areas with plant species targeted at increasing long term stabilization as compared to existing vegetative conditions.	Phytostabilization has the potential to be effective at stabilizing the soils and reducing transport of impacted soils. However, this technology used alone would not be effective at reducing site contaminant levels and/or exposure to site receptors. This could be effectively be used in conjunction with other remedial technologies.	Revegetating soils with species that are targeted at soil stabilization is generally considered implementable at the Site. There may be certain areas of the site that may not support the phytostabilization species (due to slopes, percent soil coverage, and soil conditions). Plant species and potential locations would be determined during the remedial design process.	Costs include the costs of the individual plants, planting, and limited O&M. O&M is considered moderate the first 3 to 5 years, or until the vegetation is considered to be established. O&M is considered to be low once the vegetation has been established. Costs are considered moderate compared to other technologies.	Not being retained for further evaluation.
7	Phytoremediation	Phytoremediation consists of planting vegetation that can uptake the contaminants located in the soil and subsequently remediate the soils. Plants and/or trees would be selected that are able to bioaccumulate and/or degrade the site contaminants.	Phytoremediation is potentially effective at remediating site contaminants. Contaminant reduction would take several years to achieve and would not immediately reduce potential exposure to site receptors. A preliminary remedial design evaluation would be required to determine if the naturally existing conditions at the site (e.g., humidity, access to groundwater, soil conditions) could support phytoremediation plant species.	Assuming that the naturally occurring site conditions can support phytoremediation plant species, phytoremediation is generally considered implementable at the Site. There may be certain areas of the site that may not support the phytoremediation species (due to slopes, percent soil coverage, access to groundwater, and soil conditions).	Costs include the cost of the individual plants/trees, planting, and O&M. O&M is considered moderate to high, as remediation of the site contaminants is directly dependent on the success of the plants/trees to thrive over an extended period of time. Costs are considered moderate to high as compared to other technologies.	Not being retained for further evaluation as a standalone technology. Being retained as a potential component to another technology.
8	Electrokinetic Remediation	Electrokinetics is based on the principle that when direct current (DC) is passed through contaminated soil, certain (negatively charged) types of contaminants will migrate through the soil pore water to a place where they can be removed. This alternative uses electrode assemblies that are installed in the ground in a square array and connected to a DC voltage power supply. Each electrode assembly contains water, a pump, an electrode, and various controllers and sensors. The outer casing of the electrodes is made of porous ceramic through which the electrical current and contaminants pass. A vacuum is applied to the casings which keeps the water inside the assembly from flowing out and saturating adjacent soils.	Overall effectiveness of using electrokinetic remediation would need to be determined by conducting a pilot and potentially a bench scale treatability study. Factors that would be evaluated during the treatability studies would include, but would not be limited to, voltage rates, effectiveness in soils with low moisture content, and the increased acidity to the treated soil.	Electrokinetic remediation has not been tested at the site, so currently is considered low for implementablility. A pilot treatability study would need to be conducted to determine if the low soil moisture content in the soil would support the removal of copper and if the increased soil acidity would impact vegetative species.	The cost associated with electokinetic remediation is assumed to be moderate to high. Factors such as the spacing and number of electrodes would be determined during a pilot treatability study, could greatly impact the costs for this technology. Therefore, without the results of a pilot study the overall cost of implementation cannot be determined.	Not being retained for further evaluation

TABLE 5-2
SURFACE WATER REMEDIAL TECHNOLOGIES

FREEPORT-MCMORAN CHINO MINES COMPANY
VANADIUM, NEW MEXICO
SMELTER/TAILING SOILS IU FEASIBILITY STUDY

NO.	REMEDIAL TECHNOLOGY	DESCRIPTION	PRELIMINARY SCREENING			CONCLUSION
			EFFECTIVENESS	IMPLEMENTABILITY	COST	
1	No Action	No further active response actions for surface water.	Contaminants will naturally attenuate over time. Does not provide additional mechanisms to prevent contaminant exposure to site receptors.	Is considered implementable.	There are no costs associated with no action.	Being retained for baseline comparison of remedial technologies.
2	Monitoring	No further active response actions for surface water. Monitoring to be conducted to prove the occurence of natural remediation.	Contaminants will naturally attenuate over time. Does not provide additional mechanisms to prevent contaminant exposure to site receptors.	Is considered implementable.	Costs are associated with types of monitoring (quantitative and/or qualitative) and monitoring durations selected.	Being retained for evaluation as a part of a remedial alternative.
3	Excavation (In-Drainage, Upland, or Stock Ponds)	Excavation includes removing impacted in-drainage sediments and/or upland soils determined to be contributing to surface water impacts.	Is considered highly effective at reducing the presence of site contaminants.	Is considered to be generally technically implementable with the exception of certain areas of the site that are more difficult to access with equipment and personnel due to terrain conditions and presence of mature trees.	Costs include equipment use and maintenance, material handling and transport, and characterizaiton and final disposition. Long term O&M costs related to BMPs are considered to be low to moderate.	Being retained for evaluation as a part of a remedial alternative.
4	In-Stream Removal of Suspended Sediments	Consists of construction of settling basins within the stream drainage areas to allow for sediments to descend to bottom of the pool and accumulate. Accumulated impacted sediments would be removed by mechanical methods.	Is considered to be effective at capturing contaminated sediments. Settling pools currently exist on site and have demonstrated effectiveness in capturing contaminated sediments	Is considered to be technically implementable. Some portions of drainage areas may be restricted from construction of pools due to equipment accessibility restrictions.	Costs are considered to be moderate during construction of the settling pools. Long term O&M costs are considered to be moderate to high as compared to excavation and surface water treatment.	Being retained for evaluation as a part of a remedial alternative.
5	Limestone Treatment	Consists of installation of features, such as limestone, within the surface water drainage pathway. As the surface water passes over the feature (e.g., limestone) the pH is elevated, subsequently making the contaminants (copper) less bioavailable to site receptors.	Is considered effective at raising surface water pH as long as surface water makes contact with the limestone features.	Is considered to be technically implementable. Some portions of drainage areas may be restricted from installation of limestone features due to equipment accessibility restrictions.	Costs are considered to be high during construction of the limestone features. Long term O&M costs are considered to be low compared to excavation and in-stream removal of suspended sediments.	Being retained for evaluation as a part of a remedial alternative.
6	Alkaline Washing	Consists of insertion of alkaline fluid into the sediments and banks of the drainage. The alkaline wash will raise pH and sequester metals in the sediments, subsequently reducing mobilization of the contaminants (copper) to surface water.	Is considered effective at raising pH and lowering metals concentraitons in surface water as long as the majority of metals loading is coming from sediments.	Is considered to have low implementability. There are large infrastructure requirements and some portions of the drainage area may be restricted due equipment accessibility restrictions.	Costs are considered to be high both during the construction and O&M phases when compared to other remedial options.	Not being retained for evaluation as a part of a remedial alternative.
7	Sediment and Erosion Control	Consists of construction of ditches, berms, and other controls (e.g., sedimentation controls) to prevent surface water run-on to the impacted areas and run-off from the impacted areas.	Is considered effective at minimizing the transport of contaminants to and from the drainage areas and surface water.	Is considered to be technically implementable in the drainage area and upland portions of the Site with exception to areas that may be inaccessible to equipment and personnel.	Construction costs are considered to be low to moderate. Long term O&M costs associated with maintenance, repair, and replacement of controls are considered to be low to moderate compared to other surface water remedial technologies.	Being retained as a component of remedial alternatives.

FREEPORT-MCMORAN CHINO MINES COMPANY
VANADIUM, NEW MEXICO
SMELTER/TAILING SOILS IU FEASIBILITY STUDY PROPOSAL

ALT	DESCRIPTION	OVERALL PROTECTION	COMPLIANCE WITH ARARs	LONG-TERM EFFECTIVENESS AND PERMANENCE	REDUCTION OF TOXICITY, MOBILITY OR VOLUME	SHORT-TERM EFFECTIVENESS	IMPLEMENTABILITY	COST EFFECTIVENESS	NMED ACCEPTED	COMMUNITY ACCEPTANCE	GREEN REMEDIATION
1	No Action	Does not provide any form of overall protection of human health and the environment. Does not meet the RACs.	Is not compliant with ARARs.	Not effective in the long-term or permanent.	Does not reduce toxicity, mobility or volume.	Not effective in the short-term.	Is implementable at the site, as no action is required.	There are no costs associated with this alternative.	Not applicable at this time	Not applicable at this time	No additional resources would be required to implement this alternative.
2	Monitoring	The ability of the this alternative to satisfy this criterion is low, as copper concentrations are not anticipated to decrease over time.	The likelihood of compliance with the ARARs on an ongoing basis is low.	The effectiveness of this remedial alternative in the long-term is limited, although natural attenuation may lower copper in soils due to erosion and availability to wildlife due to depositon over time. It may not reduce concentrations to below human health of avian risk values. However, this alternative affords the opportunity to continue data collection and to take additional action if necessary.	Does not reduce toxicity, mobility, or volume, but may reduce accessibility if eroded from site or covered by soil deposition over time.	Not effective in the short-term.	This remedy is implementable at the site with limited additional effort.	Capital Costs: $147K O&M (NPV, 30 yr): $1.1MM TIC: $1.3MM			Emissions and fuel use would be limited to those associated with light vehicles and sample shipping/analysis. This alternative would save exisiting vegetation from destruction.
3	Excavation and Monitoring	Removal of all soil concentrations above RAC would satisfy all requirements for protecting human health and the environment.	Compliant with applicable standards.	Removal of contaminated soil would be effective long-term and would be permanent.	Reduces toxicity, mobility, and volume of the concentration of metals in surface soil. However, does not reduce the toxicity, volume, or mobility due to treatment.	This alternative is considered effective in the short-term. Normal risks associated with nuisance dust, noise, and traffic.	Based on the location of the human health and avian exposure units, excavation and monitoring is implementable. Since the concentrations of metals is limited to the top six-inches of soil, the amount of soil would be limited over the exposure areas. Monitoring of avian risk across exposure areas would be required.	Capital Costs: $9.0MM O&M (NPV,30yr): $1.2MM TIC: $10.2MM			Additional emissions and fuel use would be required to excavate the material from the exposure areas. The material would be reused and recycled. This alternative would result in destruction of existing vegetation.
4	Containment and Monitoring	Soil cover would eliminate direct human and avian contact with the contaminants. The pathways would only be closed if the soil cover remains in place. The soil cover could be breached by digging, construction, or similar activities. This could potentially pose a risk to human health or avian species.	Compliant with applicable standards.	A soil cover would require long-term operations, maintenance, and monitoring to continue to be effective. A soil cover would be considered a moderately effective solution.	The toxicity and volume of the material would not decrease with the addition of a soil cover. The mobility of the contaminants by either wind erosion, overland flow, or infiltration would be reduced.	This alternative is considered effective in the short-term, similar to Alternative 3.	The implementability of this alternative is similar to Alternative 3. The exception of this alternative is the long-term monitoring and maintenance that is required with this option.	Capital Costs: $23.0MM O&M (NPV,30yr): $1.2MM TIC: $24.2MM			Emissions and fuel use would be similar to Alternative 3 (hauling in clean cover and capping the impacted soil rather than excavating impacted soil and hauling to an operation area). This alternative would result in destruction of existing vegetation.
5	Soil Amendments and Monitoring	The remedy alternative does not address the risk from total metals concentrations. Therefore, it is not protective of human health or the environment.	The likelihood of compliance with ARARs on an going basis is low.	This remedy would not address long-term effectiveness of risk to human health and avian risk.	This liming remedy would reduce toxicity and the bioavailability of the metals, although the effectiveness is less after the white rain unless pH is low (e.g., < 2); the remedy would not address the direct contact or ingestion pathways. No benefit is expected from the organic matter application based on results of the amendment study.	Based on the results from the soil amendment study, this remedy would take several years to implement.	The implementability of this alternative is less than the implementability of the excavation or containment alternatives.	Capital Costs: $1.7MM O&M (NPV,30yr): $1.2MM TIC: $2.9MM			Emissions and fuel use would be lower than Alternatives 3 and 4. Similar equipment would be used to till in the lime, but far less lime would be required and the associated haulage would be vastly reduced. This alternative would result in destruction of existing vegetation.

TABLE 7-2
DETAILED EVALUATION OF THE REMEDIAL ALTERNATIVES - SOILS (pCu)

FREEPORT-MCMORAN CHINO MINES COMPANY
VANADIUM, NEW MEXICO
SMELTER/TAILING SOILS IU FEASIBILITY STUDY PROPOSAL

LTERNATIV	DESCRIPTION	OVERALL PROTECTION	COMPLIANCE WITH ARARs	LONG-TERM EFFECTIVENESS AND PERMANENCE	REDUCTION OF TOXICITY, MOBILITY OR VOLUME	SHORT-TERM EFFECTIVENESS	IMPLEMENTABILITY	COST EFFECTIVENESS	NMED ACCEPTED	COMMUNITY ACCEPTANCE	GREEN REMEDIATION
1	No Action	Does not provide any form of overall protection for ecological receptors. Does not meet the RAOs.	Is not compliant with ARARs.	Not effective in the long-term or permanent.	Does not reduce toxicity, mobility, or volume.	Not effective in the short-term.	Is implementable at the site, as no action is required.	There are no costs associated with this alternative.	Not applicable at this time	Not applicable at this time	No additional resources would be required to implement this alternative.
2	Monitoring	The ability of this alternative to satisfy this criterion is low; however, due to the presence of naturally occurring calcium carbonate, natural attenuation may be occuring at the site. The rate of natural attenuation is currently unknown but was enhanced by the 2008 white rain.	The likelihood of compliance with the ARARs on an ongoing basis is low.	The effectiveness of this remedial alternative in the long-term is dependent on natural attenuation. A natural attenuation rate for the remediation of pCu has not be determined at this point. However, this alternative affords the opportunity to continue data collection and to take additional action if necessary.	Based on the amendment, pH and insect studies, the white rain in 2008 decreased cupric ion activity (increased pCu), reduced copper uptake into plants and thus reduced phytotoxicity, and improved plant richness.	A natural attenuation rate has not been determined for pCu. Improvements to pCu soils beyond the improvement in 2008 from the white rain are not anticipated in the short-term to meet RAOs.	This remedy is implementable at the site with limited additional effort.	Capital Costs: $357K O&M (NPV, 30 yr): $1.4MM TIC: $1.7MM			Emissions and fuel use would be limited to those associated with light vehicles and sample shipping/analysis. This alternative would save exisiting vegetation from destruction.
3	Excavation and Monitoring	Removal of low pCu soils would meet overall protection for ecological receptors.	Compliant with applicable standards.	The effectiveness of this remedial alternative in the long-term is high to increase pCu values. Once excavation of historically deposited soils are removed, the source of the material would be removed. Short term monitoring and sampling may be required to document that the excavation was sufficient.	Reduces toxicity, mobility, and volume of the concentration of pCu in surface soil. However, does not reduce the toxicity, volume, or mobility due to treatment.	This alternative is considered effective in the short-term. Normal risks associated with nuisance dust, noise, and traffic.	The implementability of this alternative is considered moderate compared to other alternatives. Excavation would not be implementable in areas of bedrock outcrops or steep slopes. The presence of these two physical factors limits the implementability of this alternative.	Capital Costs: $4.1MM O&M (NPV, 30 yr): $1.4MM TIC: $5.5MM			Additional emissions and fuel use would be required to excavate the material. The material would be reused and recycled. This alternative would result in destruction of existing vegetation.
4	Tilling and Monitoring	The ability of this alternative to satisfy this criterion is moderate. Natural attenuation rates for pCu have not been determined, but tilling would increase the rate of natural attenuation compared to monitoring only.	The likelihood of this alternative to meet the ARARs of an ongoing basis is considered moderate.	The long-term effectiveness of this alternative is considered moderate to increase pCu values.	This alternative would increase the amount of volume, by mixing the top soil layers with underlying soils. Mobility and toxicity may be reduced.	This alternative is considered moderately effective in the short-term. There is currently some but limited data regarding the effectiveness of tilling.	The implementability of this alternative is considered moderate. It has the same limitations as Alternative 3, and could not be used in areas of bedrock outcrops or steep slopes. Ths physical limitations of this alternative limit the overall effectiveness due to the limited application area.	Capital Costs: $1.2MM O&M (NPV, 30 yr): $1.4MM TIC: $2.6MM			Emissions and fuel use would be lower than Alternative 3. A medium-sized dozer with a ripper could implement this alternative with relatively lower fuel use and less support requirements. This alternative would result in destruction of existing vegetation.
5	Soil Amendments, Tilling, and Monitoring	The ability of the this alternative to satisfy this criterion is moderate. Natural attenuation rates for pCu have not been determined, but tilling would increase the rate of natural attenuation compared to monitoring only.	The likelihood of this alternative to meet the ARARs on an ongoing basis is considered moderate.	The long-term effectiveness of this alternative is considered moderate to high to increase pCu values. Lime (calcium carbonate) has been shown to increase pCu values at the site. However, additional applications of soil amendments may be required in bedrock outcrops or on steep slopes due to transportation of material from storm water flows.	This alternative would increase the amount of volume, by mixing the top soil layers with underlying soils. Mobility and toxicity should be reduced by addition of either lime, organic material, or other.	This alternative would be considered moderately effective in the short-term, as it may take several years for the soil amendments to increase the pCu values.	The implementability of soil amendments is considered high compared to the other alternatives. It is an alternative that could be applied to areas with steep slopes and bedrock outcrop areas, which cannot be addressed by physical means. Additional applications of soil amendments may be required in the future in bedrock outcrops or steep slopes due to the transporation of amendments in storm water.	Capital Costs: $1.9MM O&M (NPV, 30 yr): $1.4MM TIC: $3.3MM			Emissions and fuel use would be lower than Alternative 3 but higher than Alternative 4. This alternative would result in destruction of existing vegetation.
6	Partial Excavation, Soil Amendments, Tilling, and Monitoring	The overall protection of this alternative would be high, as it would address the largest area of pCu values of any of the alternatives.	The likelihood of this alternative to meet the ARARs on an ongoing basis is considered moderate to high.	The long-term effectivness for this alternative is considered to be high compared to the other alternatives. It addresses the largest area, removes source material, and minimizes the amount of long-term monitoring and maintenance.	Reduces toxicity, mobility, and volume of the concentration of cupric ion activity (increasing pCu) in surface soil from excavated areas. Soil amendment areas with lime in very low pH soils would reduce toxicity and potential mobility of remaining soils. Tilling would increase the volume of material, but would decrease the mobility and toxicity.	This alternative would be considered to be moderately effective in the short-term. It would address all of the pCu areas, and would have a high short-term effectiveness for the excavated areas.	The implementability of this alternative is considered the most difficult to implement almongst all of the alternatives. It has the highest area of implementation compared to other remedial alternatives. Amendments could be applied to areas with steep slopes and bedrock outcrop areas, but excavation would not be implementable in areas of bedrock outcrops or steep slopes.	Capital Costs: $2.9MM O&M (NPV, 30 yr): $1.4MM TIC: $4.3MM			This alternative would result in the highest emissions and fuel use of the six alternatives, as it is a combination of Alternatives 3 through 5. This alternative would result in destruction of existing vegetation.

TABLE 7-3
DETAILED EVALUATION OF THE REMEDIAL ALTERNATIVES - SURFACE WATER DRAINAGES

FREEPORT-MCMORAN CHINO MINES COMPANY
VANADIUM, NEW MEXICO
SMELTER/TAILING SOILS IU FEASIBILITY STUDY PROPOSAL

LTERNATIV	DESCRIPTION	OVERALL PROTECTION	COMPLIANCE WITH ARARs	LONG-TERM EFFECTIVENESS AND PERMANENCE	REDUCTION OF TOXICITY, MOBILITY OR VOLUME	SHORT-TERM EFFECTIVENESS	IMPLEMENTABILITY	COST EFFECTIVENESS	NMED ACCEPTED	COMMUNITY ACCEPTANCE	GREEN REMEDIATION
1	No Action	Does not provide any form of overall protection of human health and the environment. Does not meet the RAOs.	Is not compliant with ARARs.	Not effective in the long-term or permanent.	Does not reduce toxicity, mobility, or volume.	Not effective in the short-term.	Is implementable at the site, as no action is required.	There is no costs associated with this alternative.	Not applicable at this time	Not applicable at this time	No additional resources would be required to implement this alternative.
2	Monitoring	The ability of this alternative to satisfy this criterion is low; however, long-term protection of aquatic receptors may be achieved if upstream sources of contaminants from either suspended sediments or dissolved metals concentrations in storm water flow are addressed. At this time, the loading rates or rates of contribution from either of these sources is unknown.	The likelihood of compliance with the ARARs on an ongoing basis is low to moderate, and is dependent on the management of upstream sources, suspended sediment and dissolve metals concentrations, as well as overall water quality.	The effectiveness of this remedial alternative in the long-term is limited to reduce concentrations to below aquatic life standards. However, it may be effective enough to address long-term risks if upstream sources of contaminants are addressed. Additionally, this alternative affords the opportunity to continue data collection and to take additional action if necessary.	Does not reduce toxicity, mobility, or volume.	Not effective in the short-term.	This remedy is implementable at the site with limited additional effort. Long-term monitoring would be required to show improvements in water quality in the surface water drainages.	Capital Costs: $130K O&M (NPV, 30 yr): $432K TIC: $587K			Emissions and fuel use would be limited to those associated with light vehicles and sample shipping/analysis. This alternative would save exisiting vegetation from destruction.
3	Excavation and Monitoring	This ability of this alternative to meet the overall protection of water quality is high to moderate. The overall protection is based on the removal of historical sediments, but also a reduction potential upstream contributors. The overall protection is also based on the alternatives selected in Table 7-2 and Table 7-4. Long-term monitoring is suggested for the implementation of this alternative.	The likelihood of compliance with the ARARs on an ongoing basis is moderate to high with this alternative. This is the potential for reduced long-term effectiveness of this alternative if upstream contribution continue. Additional excavation may be required at a future time.	The effectiveness of this remedial alternative in the long-term is high to moderate to reduce concentrations to aquatic life standards. Once excavation of historical sediments is complete, monitoring will be required to document that water quality criteria have been met. Long-term effectiveness of this alternative may be dependent on addressing upstream contributors (suspended sediments and storm water).	This alternative does not address toxicity reduction, but it does reduce the mobility of the contaminants by removing them from contact with surface water. The volume of material will be reduced and also prevent potential contamination of surface water due to the presence of historical sediments.	This alternative is considered moderately effective in the short-term. Surface water quality may take some time to improve. Normal risks associated with nuisance dust, excavation hazards, noise and traffic.	In specific surface water drainages this alternative will potentially be difficult to implement compared to other alternatives. Specifically in the Bolton Spring and Ash Spring corridor the excavation of historical sediments may do more harm than good to the ecological habitat. Additional permitting and coordination would be required compared to other alternatives. For other drainages the excavation of historical sediments is considered implementable. Some of the drainages may not be accessible to large equipment, due to steep slopes or tight access. However, overall this alternative is implementable at the site. No special equipment is required to complete this alternative. Equipment and materials to complete the job are readily available.	Capital Costs: 3.6MM O&M (NPV, 30 yr): $544K TIC: $4.1MM			Additional emissions and fuel use would be required to excavate the drainages. The constrained environment would also redcue efficiency. This alternative would result in destruction of existing vegetation.
4	Excavation, Sediment Control, Limestone Treatment, and Monitoring	The likelihood of compliance with the ARARs on an ongoing basis is high, and potentially higher than Alternative 3. There is the potential for reduced long-term effectiveness of this alternative if upstream contributions continue. Additional excavation should be anticipated within the sedimentation basins in the future. The addition of limestone to treat bioavailability of copper increases the potential compliance with ARARs.	The effectiveness of this remedial alternative in the long-term is high to moderate to reduce concentrations to aquatic life standards. Once excavation of historical sediments is complete and sedimentation basins with limestone treatment is added, monitoring will be required to document that water quality criteria have been met.	The effectiveness of this remedial alternative in the long-term is high to moderate to reduce concentrations to aquatic life standards. Once excavation of historical sediments with the installation is complete and sedimentation basins are installed to collect suspended sediment monitoring will be required to document that water quality criteria have been met. Overall long-term effectiveness will also depend on any additional potential upstream sources of contaminants. Chemical treatment of the surface would increase the potential effectiveness of this alternative compared to Alternative 3.	This alternative addresses toxicity by reducing the bioavailability of copper due to the presence of limestone in the sedimentation basins. It also reduces the mobility of the contaminants by removing them from contact with surface water. The volume of material will be reduced with this alternative and it will also prevent potential contamination of surface water due to the presence of historical sediments.	This alternative is considered moderately effective in the short-term. Surface water quality may take some time to improve. Normal risks associated with nuisance dust, excavation hazards, noise, and traffic.	In specific surface water drainages this alternative will be potentially difficult to implement compared to other alternatives. Specifically, in the Bolton Spring and Ash Spring corridor, the excavation of historical sediments may do more harm than good to the ecological habitat. Additional permitting and coordination would be required compared to other alternatives due to the excavation component. Specifically for the critical habitat transect, excavation may be omitted and only limestone sedimentation basins placed in the surface water drainages. For other drainages, the excavation of historical sediments is considered implementable. Some of the drainages may not be accessible to large equipment, due to steep slopes or tight access. These factors make the implementability of this alternative more challenging than other alternatives. No special equipment is required to complete this alternative. Equipment and materials to complete the job are readily available.	Capital Costs: $4.5MM O&M (NPV, 30 yr): $1.3MM TIC: $5.8MM			Emissions and fuel use would be higher than Alternative 3, as additional sediment control measures and treatment are added, both of which increase emissions and natural resource use through manufacturing, material hauling, and maintenance. This alternative would result in destruction of existing vegetation.
5	Sediment Control, Erosion Control, and Monitoring	The ability of this alternative to meet the overall protection of water quality is low to moderate. The overall protection of this alternative is based on the control of suspended sediments and potentially dissolved concentrations in storm water. This alternative does not address historical sediments. The addition of limestone as part of the BMPs to treat dissolved/bioavailable copper would increase the potential compliance with ARARs.	The ability of this alternative to comply with this criterion is low to moderate.	The long-term effectiveness of this alternative is low to moderate. A significant amount of maintenance and monitoring will be required to implement a large enough sediment and erosion control program across all of the drainages. Potential excavation and maintenance of the BMPs would be required on a regular basis to keep this alternative effective.	This alternative does not reduce the volume of material within the drainages. If limestone or other material is used, toxicity of the constituents may be reduced. Mobility of the constituents may be reduced.	This alternative would be low to moderately effective in the short-term. This alternative does not address the presence of historical seidments in the drainages. This alternative would take time for water quality to improve.	This alternative would be more difficult to implement compared to Alternatives 1-3, and as difficult to implement as Alternative 4. However, the erosion control measures would need to be implemented over a much larger area and would have to be monitored and maintained on a more frequent basis than Alternative 4.	Capital Costs: $4.6MM O&M (NPV, 30 yr): $4.4MM TIC: $9.0MM			This alternative would result in the highest emissions and fuel use of the five alternatives. Although excavation is removed as an activity, erosion control is added which comes with considerably more material use and maintenance. This alternative would result in destruction of existing vegetation.

TABLE 7-4
DETAILED EVALUATION OF THE REMEDIAL ALTERNATIVES - SURFACE WATER STOCK TANKS

FREEPORT-MCMORAN CHINO MINES COMPANY
VANADIUM, NEW MEXICO
SMELTER/TAILING SOILS IU FEASIBILITY STUDY PROPOSAL

LTERNATIV	DESCRIPTION	OVERALL PROTECTION	COMPLIANCE WITH ARARs	LONG-TERM EFFECTIVENESS AND PERMANENCE	REDUCTION OF TOXICITY, MOBILITY OR VOLUME	SHORT-TERM EFFECTIVENESS	IMPLEMENTABILITY	COST EFFECTIVENESS	NMED ACCEPTED	COMMUNITY ACCEPTANCE	GREEN REMEDIATION
1	No Action	Does not provide any form of overall protection of human health and the environment. Does not meet the RAOs.	Is not compliant with ARARs.	Not effective in the long-term or permanent.	Does not reduce toxicity, mobility, or volume.	Not effective in the short-term.	Is implementable at the site, as no action is required.	There is no costs associated with this alternative.	Not applicable at this time	Not applicable at this time	No additional resources would be required to implement this alternative.
2	Monitoring	The ability of the this alternative to satisfy this criterion is low; however, long-term protection of aquatic receptors may be achieved if upstream sources of contaminants are addressed.	The likelihood of compliance with the ARARs on an ongoing basis is low to moderate, depending on the management of upstream sources.	The effectiveness of this remedial alternative in the long-term is limited to reduce concentrations to below aquatic life standards. However, may be enough to address long-term risks if upstream sources of contaminants are addressed. Additionally, this alternative affords the opportunity to continue data collection and to take additional action if necessary.	Does not reduce toxicity, mobility, or volume.	Not effective in the short-term.	This remedy is implementable at the site with limited additional effort.	Capital Costs: $49K O&M (NPV, 30 yr): $82K TIC: $141K			Emissions and fuel use would be limited to those associated with light vehicles and sample shipping/analysis.
3	Excavation and Monitoring	Removal of historical sediments from stock tanks would address a major contributor to aquatic risk; however, there is still the potential for long-term risk to aquatic receptors due to upstream contribution from either suspended sediments or dissolve metals concentrations in surface water.	The likelihood of compliance with the ARARs on an ongoing basis is moderate to high with this alternative. There is the potential for reduced long-term effectiveness of this alternative if upstream contributions continue. Additional excavation may be required at a future time.	The effectiveness of this remedial alternative in the long-term is high to moderate to reduce concentrations to below aquatic life standards. Once excavation of historical sediments is complete, monitoring will be required to document that water quality criteria have been met.	This alternative does not address toxicity reduction, but it does reduce the mobility of the contaminants by removing them from the stock tanks and out of surface water. The volume of material will be reduced and also prevent potential contamination of surface water due to the presence of historical sediments.	This alternative is considered effective in the short-term. Normal risks associated with nuisance dust, excavation hazards, noise, and traffic. Coordination may need to be made to provide alternative water sources to tanks owners during construction.	Based on the location of the tanks and their accessibility, this alternative is implementable at the site. Equipment and materials to complete the job are readily available.	Capital Costs: $942K O&M (NPV, 30 yr): $82K TIC: $1.1MM			Additional emissions and fuel use would be required to excavate the material from the stock tanks and haul it to the operation area. The material would be reused and recycled.
4	Excavation, Limestone, and Monitoring	Removal of historical sediments from stock tanks would address a major contributor to aquatic risk, and limestone treatment from riprap or other material would decrease the bioavailability of copper for aquatic organisms. However, there is still the potential for long-term risk to aquatic receptors due to upstream contribution from either suspended sediments or dissolve metals concentrations in surface water.	The likelihood of compliance with the ARARs on an ongoing basis is high, and potentially higher than Alternative 3. There is the potential for reduced long-term effectiveness of this alternative if upstream contributions continue. Additional excavation may be required at a future time. The addition of limestone to treat bioavailability of copper is stock tanks increases the potential compliance with ARARs.	The effectiveness of this remedial alternative in the long-term is high to moderate to reduce concentrations to aquatic life standards. Once excavation of historical sediments is complete and limestone treatment is added, monitoring will be required to document that water quality criteria have been met.	This alternative decreases the toxicity of copper in surface water by potentially reducing the bioavailability of copper as well as removing historical sediments. This alternative also reduces the mobility of the contaminants by removing them from the stock tanks and out of surface water. The volume of material will be reduced and also prevent potential contamination of surface water due to the presence of historical sediments.	This alternative is considered effective in the short-term. Normal risks associated with nuisance dust, excavation hazards, noise, and traffic. Coordination may need to be made to provide alternative water sources to tanks owners during construction.	Based on the location of the tanks and their accessibility, this alternative is implementable at the site. Equipment and materials, including limestone riprap and/or blocks are readily available in the area to complete the job.	Capital Costs: $1.1MM O&M (NPV, 30 yr): $82K TIC: $1.2MM			This alternative would generate slightly more emissions and consume more fuel than Alternative 3 in that lime would need to be hauled to the stock tanks and spread using equipment.

Dear Mr. Yurdin:

Re: Amendment Study Plots Year 5 Monitoring Report for the Smelter Tailing Soils Investigative Unit – Chino AOC

Freeport-McMoRan Chino Mines Company (Chino) submits under separate cover the *Year 5 Monitoring Report for Smelter Tailing Soils Investigative Unit (STSIU) Amendment Study Plots*, under the Chino Administrative Order on Consent (AOC). The report provides the data collected for the fifth and last year of monitoring as well as the evaluation of all five years of the data collected for the study. The report was submitted today to Mr. David Mercer.

Please contact Ms. Alicia Voss at (602) 366-8049 with any questions or comments concerning this report.

Sincerely,

Brian D. McGill

Executive Summary

The soil in some areas of the Smelter and Tailing Soil Investigation Unit (STSIU) at the Chino Mine in New Mexico is characterized by depressed pH and elevated copper concentrations. Freeport-McMoRan Chino Mines Company (Chino) submitted an Amendment Study Work Plan for the STSIU (Work Plan) to the New Mexico Environment Department (NMED) in 2006, finalized in 2008 (Arcadis 2008), and approved by NMED in 2008 (NMED 2008). The approved Work Plan summarizes the study design for the evaluation of three remedial technologies (application of lime, organic matter, and tilling to the soil) and their potential application to the STSIU. The evaluation is a pilot-level effort that includes qualitative and quantitative analyses to provide a preliminary recommendation of the usefulness of each of these technologies for remediating the soil.

When this study was originally proposed and defined, the goal was to test the remedial technologies for effectiveness and permanence of the remediation to: (1) reduce risk of copper exposure to small, ground-feeding birds, and (2) improve habitat and rangeland for wildlife and livestock. After the Work Plan was formally approved and implemented, NMED issued revised pre-feasibility study remedial action criteria (pre-FS RAC) for the STSIU in March 2011, which, along with other factors,[1] changed the study. The copper pre-FS RAC is the threshold for total soil copper concentration that may be hazardous to small ground-feeding birds (1,600 milligrams per kilogram [mg/kg]), and the pCu pre-FS RAC is a threshold for a soil-based metric called cupric ion activity[2] for the

---

[1] The study objectives, specifics of the remedial techniques, monitoring approach, and methods described in the approved Work Plan were modified due to: (1) field constraints, (2) establishment of the pre-FS RAC for plants, (3) a white rain event that altered the soil chemistry, (4) observed greater soil variability on study plots than expected, and (5) comments from NMED. These modifications, implemented over the course of the pilot study, are described in each annual Amendment Study report or in this report (Arcadis 2010b, 2011b, 2012, 2013; in particular, see Appendix A of the Year 2 Amendment Monitoring Report, ARCADIS 2011b). Amendments and/or tilling were applied to three test plots on June 17 and 18, 2008 and conditions monitored semi-annually until October 2013. **Table 1** outlines changes that occurred in the study design and monitoring over time.

[2] Cupric ion activity is referred to as pCu, where pCu = $-\log\{Cu^{2+}\}$, and meets criteria requirements when pCu is greater than or equal to 5 in areas where the total copper

protection of wildlife habitat and rangeland for livestock. Through reclamation borrow activities and interim remedial actions in the STSIU, currently Chino believes that there is little to no area remaining with impacts above the pre-FS RAC copper concentration for birds. Soil in large areas has been removed and re-seeded to meet the reclamation need for borrow areas to cover tailings. The pending STSIU Feasibility Study (FS) will delineate reclaimed areas and evaluate and define additional small areas if concentrations are still present that exceed pre-FS RAC. The three technologies evaluated in this report, therefore, will potentially be used to improve wildlife habitat and livestock rangeland areas and secondarily to reduce risk to birds via a reduction in plant uptake of copper and the subsequent reduction of copper exposure to birds.

The primary objectives of this study were to test the effectiveness of lime, organic matter, and/or tilling in: (1) increasing and then stabilizing pH and pCu, (2) reducing copper uptake into plants, and (3) improving the vegetative community structure and composition for wildlife and livestock. Results of this study will be used to determine if amending copper-impacted soils using lime and/or organic matter, with or without tilling, should be advanced to full-scale implementation via the STSIU FS. The primary metrics used to assess the effectiveness of the remedial technologies in this pilot study are pCu, plant uptake of copper, plant species richness, percent vegetative cover, and plant species composition.

The pilot study was performed on four square 0.25-acre plots. In June 2008, two plots were amended with lime (1.3 tons/acre [t/ac]) and organic matter (as manure) and subsequently tilled (East and North amendment plots), one plot was amended with lime (1.3 t/ac) and organic matter without tilling (Northeast amendment plot), and one was a control plot without amendments or tilling (West control plot). Three levels of organic matter were tested for performance, with the highest application rate (72 t/ac) on the Northeast plot, a mid-level rate (47 t/ac) on the East plot, and lowest rate (24 t/ac) on the North plot (see **Table 1: Study Design Revised in March 2008**). No treatments were performed without organic matter additions. The plots were located on different qualities of rangeland (poor on East plot and fair or good to fair on the

---

concentration is greater than 327 mg/kg (<327 mg/kg is soil background concentration, and pCu criteria is not needed for such low copper areas). Note: an increase in pCu is a reduction in cupric ion activity and potential phytotoxicity. Though pCu was measured using selective electrode potential for a subset of the data, the analyses in this report were based on pCu estimated from predictive regressions ($r^2 = 0.97$) of total copper and pH.

others) and slope conditions (steep [≥13%] slope on Northeast, relatively level slopes on others) to evaluate the appropriateness of the technologies across a broad spectrum of upland environments. Each study plot represented a different combination of the three technologies and environmental conditions (i.e., each is a single replicate of treatment combinations) but was paired with a nearby untreated reference plot for comparison. Treated plots were not seeded.

Success of the remedial technologies was gauged using the primary metrics. Success is defined as an increase in soil pCu, decrease in copper concentration in plant tissue, an increase in plant species richness and cover, an increase in rangeland grass cover, and a reduction in undesirable plant species (toxic, non-native). Additionally, re-establishment of the vegetation community after tilling or disturbance from placing amendments on plots was evaluated using the mine’s reclamation success criteria (Daniel B. Stephens & Associates, Inc. 1999 and Chino 2007). Of these, the vegetation community parameters’ response to the chemistry changes (not the soil chemistry) were the most important metrics for evaluating remediation success because the objective of the remediation is to improve wildlife habitat and rangeland for livestock.

A range of supporting (“secondary”) metrics was used to interpret the study findings. Secondary metrics were soil pH (higher pH reduces copper availability to plants), total soil copper, and acid generation potential of soil. Total organic carbon (TOC), carbon to nitrogen ratio (C:N), and supplemental nutrient data (e.g., nitrogen species) were secondary metrics that affect cover and richness. Water-soluble copper concentration determined by synthetic precipitation leaching procedure (SPLP) was also used as a secondary metric to gauge amendment success by evaluating the potential mobility of copper from soils upon contact with natural precipitation. Vegetation re-establishment and other diversity measures (Shannon diversity and evenness) supplemented the primary vegetation metrics by informing decisions on whether the remedial technologies caused more harm than good to the vegetation community.

The pilot study was designed to determine the most effective combination of the three treatments (lime, tilling, organic matter) tested, with the intent to further investigate which individual treatments were most effective once the best combination is identified. To evaluate each treatment’s effectiveness separately, evidence from two other events was gathered: (1) a “white” rain event in January 2008 and (2) a haul road ripping event in 2003. For the first, an alkaline “white” rain fell on the amendment plots before treatment in January 2008, altering soil chemistry (higher pH). This unanticipated event confounded interpretation of the pilot study results because it effectively limed the site and elevated soil pH right before treatment with lime was planned in May 2008.

However, the event provided an opportunity to evaluate the effect of lime additions without vegetation community disturbance, tilling, or organic amendments. The haul road reclamation in 2003 provided information on the effect of tilling without amendments. Haul roads traversing poor rangeland areas were ripped to a depth of 12 to 18 inches with no amendments or seeding applied (similar to tilling of the North plot and ripping of the East plot; for the purposes of this report, ripping is hereafter included as part of the definition of "tilling"[3]). Photographs and observations of the results of haul road ripping were reviewed. Changes in the amendment plots that differed from changes seen with the white rain liming and haul road reclamation were evaluated as to whether they could be ascribed to organic matter additions on the amendment plots.

For the pilot study, the conclusions on the effectiveness of the tested remedial technologies in improving pCu and plant community parameters when applied individually or in combination are based on comparing responses of treated plots and adjacent reference plots, as well as interpreting the results of the ancillary white rain and haul road ripping events.

The results of these comparisons and additional events will help inform decisions on the individual remedies and combination of remedies that might be best for the STSIU. The main conclusions drawn from the Amendment Study and recommendations on when and where to use each remedial technology are summarized in the following subsections.

Lime

The 2008 white rain event was effective at: (1) increasing pCu, (2) decreasing plant uptake of copper, and (3) improving plant community richness. The white rain was particularly effective on the level plots that were not located on steep slopes, whether in poor or fair rangeland. The pH monitoring program (Arcadis 2017a) evaluated the persistence of the improvement in pH and pCu from the white rain, and demonstrated that the improvement has been sustained after 5 years, consistent with the results of this study. Low pCu plots in the relatively level areas improved to pCu above 5 or near 5. In areas exhibiting continual improvement in pCu, monitoring natural attenuation is recommended as the best remedial technique.

---

[3] Whether tilled or ripped depended on rockiness of soil, where the rockier site was ripped.

More time may be needed to statistically demonstrate if pCu is increasing in some areas. While the white rain event did not result in the establishment of plant species that are potentially toxic or of low value to wildlife or livestock, vegetation cover was not increased enough to show benefit to wildlife habitat or improved rangeland quality. Overall, lime alone does not appear to change the community enough to enact the plant community changes desired.

Combined Technologies

While the white rain even was effective, the remedial technologies applied after the white rain were not as effective above and beyond the white rain effect. When all three technologies were combined (lime, organic matter, tilling) on the relatively level plots, pH was increased (with 90 percent confidence). However, the three technologies did not significantly improve soil pCu. Possibly the lack of significant change in pCu overall may have been due to high variability in pCu resulting from heterogeneity of the field soils, sampling error, analytical error, and using an equation to calculate pCu.

In parallel with the insignificant change in pCu, reduction in copper uptake into plants from the three technologies combined also was minimal, as the white rain was responsible for most of the reduction in the copper uptake. Tilled plots (to 8 inches deep) did not show improved pCu relative to untilled plots in the study. The effect of tilling deeper (to 12 to 18 inches) on the plant community was demonstrated by an example outside this specific study. A haul road traversing poor rangeland condition with no vegetation initially was tilled, and that action did result in high abundance of diverse grasses after 11 years. This example supports the concept that vegetation changes could be from decompacting the soil on the road.

The finding on amendment plots of no clear benefit from all three treatments (in increasing pCu and decreasing uptake of copper in plants after the white rain) suggests that chemical changes from mixing are not the driver of the large community changes, but rather that tilling physically decompacts soil, allowing plants to re-establish on poor rangeland. In contrast, the fair rangeland on relatively level ground undergoing the same treatments did not increase in cover or richness and reversed succession toward an earlier seral stage with loss of grasses. The fair rangeland plot on steeper ground also experienced a setback in succession to an earlier stage with a loss of desirable grasses. Unlike the poor rangeland plot, these areas already had a diverse plant community and rangeland grasses present, even before the white rain, despite a low pCu of approximately 2 to 3 at that time.

The benefit from decompacting soil by tilling is large and should be considered as a remedial technology after evaluating the appropriate depth in the FS. However, it is warranted only if erosion of surface soil resulting in a compacted or rocky surface was caused by a loss of the roots of a plant community impacted by pCu in the past, rather than from overgrazing. Lime does not need to be combined with tilling, unless it is required for effectiveness in very low pCu areas (< 2).

Amendment with Organic Matter

Organic matter, in combination with the other technologies, did not improve pCu or reduce copper uptake significantly. Organic matter may have exacerbated annual weed invasion and slowed recovery after the plots were disturbed from tilling or amendment application. Unlike the white rain effect alone, the disturbance from tilling combined with the effect of applying amendments in the form of lime and organic matter increased undesirable annual weeds substantially (e.g., golden crownbeard, carelessweed), some of which are potentially toxic to livestock.

At the end of 5 years, weeds increased less on the steep plot that was not tilled but also less on the haul road that was tilled (after 11 years), which suggests that factors other than tilling may have increased the invasion of undesirable weeds. However, organic matter may not be responsible because organic matter was applied at high amounts on the steeper plot with less weed invasion, and was not applied at all on the tilled haul road, which also experienced less weed invasion. The plot with less invasion was steep and subject to runoff of the organic matter, which may explain why it exhibited less invasion than the more level plots amended with organic matter. The weed invasion may be short term, as seen on the haul road that was tilled. However, after 8 years, the fair and poor rangeland plots on relatively level ground still support a fair number of potentially toxic annual weed species. Organic matter added to soils for reclamation rarely has been shown to be beneficial in arid or semi-arid areas (Paschke et al. 2005, Bay et al. 2010).Therefore, organic matter amendments are not recommended.

Steep Slopes

The three remedial technologies at the levels evaluated in this pilot study are not viable for increasing pCu in steeper areas ($\geq$ 13% slope). Tilling is not a feasible method for slopes too steep or too rough (high amount of boulders) for the equipment. It is also not feasible for areas with shallow or exposed bedrock. Liming and organic matter application were not effective at increasing pCu on steeper areas, which generally are in fair rangeland condition in the STSIU. Even the lime in the white rain had only a small effect on pCu on the steeper areas.

After disturbance from amendment application or tilling, the vegetation was successfully re-established with minimal erosion on all treated plots at the level expected for the 5-year successional stage.

Multiple Soil Categories

Guidelines for remediation of different soil categories on impacted areas of the STSIU from this assessment are as follows for the three following soil categories investigated in this report:

1. Poor rangeland with rocky soils in relatively level areas:
    - Tilling is recommended in depressed pCu areas pending further evaluation in the FS.
2. Fair to good quality rangeland with granular soils in relatively level areas:
    - Technologies evaluated in this study are not recommended.
3. Fair to good quality rangeland on steeper slopes ($\geq$ 13 percent):
    - Technologies evaluated in this study are not recommended.

Lime amendment is recommended only in poor rangeland areas with very low pH (< 2), if tilling is not found to be fully effective. These recommendations should provide the highest net environmental benefit.

The conclusions and recommendations documented in this pilot study will be considered in combination with findings from other relevant STSIU studies (Arcadis 2011a, 2017a, 2017b) to determine remedial actions that should be advanced to full-scale implementation via the FS.

1. Introduction

On December 23, 1994, Freeport-McMoRan Chino Mines Company (Chino) and New Mexico Environment Department (NMED) entered into an Administrative Order on Consent (AOC). The AOC addresses the possible environmental impacts within the defined Investigation Area (IA) at the Chino Mine in Vanadium, New Mexico (the Site) due to mining operations and historical releases. The AOC directs evaluation of remedial strategies if problems are identified. The upland Smelter and Tailing Soil Investigation Units (STSIUs) are two of the six investigation units within the IA (**Figure 1**). A draft Amendment Study Work Plan for the STSIU (Work Plan) was submitted to NMED in 2006, finalized in 2008 (Arcadis 2008), and approved by NMED in 2008 (NMED 2008). The approved Work Plan summarizes the study design for the evaluation of three remedial technologies (application of lime, organic matter, and tilling to the soil) and their potential application to STSIU.

The study objectives, specifics of the remedial techniques, monitoring approach, and methods described in the approved Work Plan were modified due to: (1) field constraints, (2) establishment of the pre-Feasibility Study Remedial Action Criteria (pre-FS RAC) for plants, (3) a white rain event that altered the soil chemistry at the Site, (4) observed higher soil variability on study plots than expected, and (5) comments from NMED. These modifications, implemented over the course of this exploratory pilot study, are described in each annual Amendment Study report or this report (Arcadis 2010b, 2011b, 2012, 2013; in particular, see Appendix A of the Year 2 Amendment Monitoring Report, ARCADIS 2011b). Four 0.25-acre amendment plots were established for the study with four adjacent 0.25-acre reference plots. Amendments (lime at the same application rate, organic matter at three application rates) and/or tilling were applied to three of the amendment plots on June 17 and 18, 2008 (the fourth plot was a control). Soil conditions were monitored semi-annually and vegetation periodically on all plots for 5 years per the Work Plan, with the final monitoring completed in October 2013. **Table 1** outlines the study, timing of sampling, and changes that occurred in the study design and monitoring over time, which are explained in more detail in Section 2.

When this study was originally proposed and defined, the goal was to test the remedial technologies for effectiveness and permanence to: (1) reduce risk to small, ground-feeding birds and (2) improve habitat and rangeland for wildlife and livestock. After the Work Plan was formally approved and implemented, NMED issued pre-FS RAC for the STSIU in September 2010. The pre-FS RAC included a 1,600 milligrams per kilogram (mg/kg) threshold for total soil copper concentrations that may be hazardous to small ground-feeding birds and a threshold for a soil-based metric called “cupric ion activity” (pCu; quantified as pCu = $-\log\{Cu^{2+}\}$ [4]) for protecting plants in wildlife habitat and livestock range. As the value of pCu decreases, cupric ion activity and potentially phytotoxicity increases. Due to reclamation borrow activities and interim remedial actions that have occurred to date in STSIU, Chino currently believes that there is little to no area remaining that is impacted above the pre-FS RAC copper concentration for birds. Soil in large areas has been removed and re-seeded to meet the reclamation need for borrow areas to cover tailings[5]. The pending STSIU FS will delineate reclaimed areas and evaluate and define additional small areas if concentrations still exceed pre-FS RAC. The technologies evaluated in this report, therefore, would likely be used primarily to improve wildlife habitat and livestock rangeland areas and secondarily to reduce risk to birds via a reduction in plant uptake of copper and the subsequent reduction of copper exposure to birds.

The primary metrics of concern to be improved with the remedial technologies evaluated in this pilot study are not only pCu, but also plant uptake of copper, plant species richness, plant cover, and plant community composition. The Site-Wide Ecological Risk Assessment (ERA) identified these vegetation parameters as potentially adversely affected by pCu (Newfields 2005). A further description of the STSIU and environmental conditions within the STSIU is provided in the STSIU Remedial Investigation Report (RI; SRK 2008), the Site-wide ERA Report (Newfields 2005), the STSIU ERA (Newfields 2008), and the approved Work Plan (Arcadis 2008).

1.1 Background on Contaminant of Concern for Plant Communities

Based on laboratory phytotoxicity studies and plant community surveys, the Site-wide ERA stated that elevated concentrations of copper, combined with depressed soil pH, may lead to a potential risk of phytotoxicity for some areas of the Chino Mine Site, which could adversely affect the wildlife habitat quality provided by the vegetation community (Newfields 2005, Arcadis 2017b). Uptake of high amounts of copper into plants can cause iron deficiency, chlorosis, and stunted growth (McBride 2001). The

---

[4] Cupric ion activity, referred to as pCu in this report, should be greater than or equal to 5 in areas where the total copper concentration is greater than 327 mg/kg to protect wildlife habitat and livestock rangeland (<327 mg/kg is background; pCu criteria are not needed for such low copper areas).

[5] See aerial photographs in Arcadis 2017a.

effects of copper on plants growing in Chino soils were shown to be highly dependent on soil pH (Newfields 2005, Arcadis 2017b). These studies also found that pCu was a predictor of potential impacts on vegetation species richness and to a lesser extent canopy cover, depending on the soil condition, slope, and amount of bedrock at a location (Arcadis 2017b). It was also noted that pCu correlated closely with differing species composition (Newfields 2005).

Estimating pCu in soil samples requires a sophisticated method using a calibrated cupric ion-selective electrode (Newfields 2005). Therefore, Newfields (2005) derived a simpler approach for estimating soil pCu using a site-specific regression equation, where pH and total copper concentration were found to be the input parameters most predictive of pCu. They developed such a regression for all areas, upland areas (with and without off-mine reference area data), and ephemeral drainage areas. For upland areas in the STSIU and upland reference areas (defined in the Site-wide ERA) that are the focus of this amendment study, the regression model using these two parameters was closely positively correlated with measured pCu values ($r^2 = 0.97$; Newfields 2005). This "upland with reference" regression model[6] was applied to all copper and pH data to predict pCu in soils for this pilot study. The method was validated during the final sampling event by measuring pCu with electrodes in October 2013 and comparing results to the predicted pCu. Hereafter, "calculated pCu" refers to pCu estimated from the Newfields (2005) regression on pH and copper, and "measured pCu" refers to pCu estimated from electrodes. When no prefix is given for presented data, pCu refers to calculated pCu.

Cupric ion activity is believed to be closely related to copper bioavailability because it measures the activity of the free copper ion (Cu^{2+}), which is the form of copper most easily taken up by plants (Barker and Pilbeam 2007). The lower the pH, the more copper converts to this free ion and becomes available to plants. The plant takes up the copper and, if it concentrates to toxic levels, may experience reduced reproduction, growth, and survival. Therefore, increasing the soil pH and reducing plant-available copper should be objectives of any selected remedial technologies.

---

[6] Calculated pCu = 7.34 + 0.93pH- 1.15 ln(Cu).

1.2 Objectives and Hypotheses Tested

Chino is exploring if the use of lime (i.e., $Ca[OH]_2$) and organic matter amendments, with or without tilling, are effective and feasible remedial actions that ameliorate the elevated copper concentrations and depressed pH in surface soils within the STSIU. The study was designed to test whether these remedial actions increase pH, reduce copper concentrations, increase pCu, increase plant community cover and richness, and improve the plant community composition to include more favorable rangeland grasses and less undesirable (non-native, toxic) species. The 5-year monitoring after treatment was designed to determine if any observed improvements are sustained.

The overall objectives of this Amendment Study are to determine the:

- Effectiveness of tilling, lime, and organic matter application as treatment methods for long-term pCu improvement and stabilization
- Effectiveness of the amendments/tilling in reducing copper uptake by plants into stems and leaves from surface soils
- Effectiveness in improving quality (richness, cover, composition) of plant communities for wildlife and livestock through the reduction of bioavailable copper
- Extent of natural re-colonization (i.e., percent native species cover and species diversity) of vegetation after lime and organic matter amendments
- Determine which remedial technology or technologies are appropriate based on rangeland conditions and slope of the site in question.

The conceptual model is summarized for each of the three technologies as follows.

- Amending with lime will increase pH by neutralizing acidity, which will decrease free copper ion activity (i.e., raising pCu; Mortvedt 2000). These changes will be sustained over the 5-year period of the study because of the low acid generation potential (AGP) in the soils. The predicted increase in pCu will result in lower concentrations of bioavailable copper, decreased plant uptake of copper and lead, and increased plant species richness and percent cover.

- Amending with organic matter will further increase pCu in proportion to amounts applied by complexing with copper (Pandey et al. 2000), making it less available to plants.

- Tilling after the application of lime and organic matter will further improve pCu by dispersing the amendments through the soil layers and mixing more alkaline, high-copper soil with the less alkaline, low-copper soil in the subsurface.

This conceptual model was tested as a series of individual hypotheses in this report (see **Table 2** for specific hypotheses). Chino recognizes that the pilot study design was not amenable to comparing the effect of each individual remedial action to fully test the conceptual model, but rather, is restricted to evaluating the various combinations and conditions representative of the few plots treated. Therefore, information was reviewed from other report and events (white rain and road haul ripping) to supplement the study and inform the final conclusions.

Results of this study will be used to determine if amendments and tilling are effective remedial actions to address the elevated copper concentrations and depressed pH in the STSIU for full-scale implementation via an FS.

1.3 White Rain Event

In the years preceding the Amendment Study, surface soils in the STSIU exhibited elevated copper concentrations and depressed pH that extended eastward following a gradient consistent with wind-blown deposition from the smelter and tailing impoundments (Newfields 2005). On January 7, 2008, several months before amendment/tilling in the study area, a white rain event took place (Arcadis 2010a). During the event, a milky alkaline rain containing calcium oxides and hydroxides (e.g., lime) was deposited across southwest New Mexico, including the Chino IA. The white rain event stretched across Grant County, NM and included Gila Cliffs Dwellings National Monument, located 40 miles north of Chino. The pH measurements in the rainwater sampled at Gila Cliffs Dwellings National Monument are likely representative of the event, which is described in detail in the white rain report (Arcadis 2017a).

A rain water pH of 7.2 was obtained at a weather station at Gila Cliffs Dwellings National Monument. The pH average in rain water measured at the weather station ranged from 4.8 to 5.3 pH over the 20 years before this event. An increase in soil pH was observed in several areas of the STSIU, including the Amendment Study area, following this white rain precipitation event. Moreover, the calcium concentration in this rain was higher than had been observed in the previous 12 years (Arcadis 2017a).

Alkaline rains are not uncommon in arid regions around the world, as soils in arid regions are often high in carbonate (CO_3^{2-}), bicarbonate (HCO_3^-), and calcium (Ca^{2+}; Zhang et al. 2012a). The chemical makeup of the precipitation is dependent on the concentrations of the soil constituents and the chemical transformations that occur during cloud formation (Mouli et al. 2005). The source of the residues in the white rain event at Chino was found to be evaporates from playas to the southwest of Chino, as evidenced by the finding that 75 percent of the residues in the white rain matched the chemical signatures of the evaporites in the Willcox playa in southeastern Arizona and the Lordsburg playa in western New Mexico (Arcadis 2017a). Although alkaline rains regularly occur in many locations, the event at Chino, with enough alkaline minerals to produce a milky appearance in the rain, appears to be an infrequent occurrence.

A comparison of surface soil samples from 0 to 6 inches below ground surface (bgs) at Chino before and after (2009) the white rain event indicated an increase in soil pH across the STSIU (Arcadis 2017a). The persistence of the effects of the white rain was monitored annually for 5 years through 2014 based on the pH Monitoring Work Plan, dated July 2010 and approved by NMED in 2010. The results of this monitoring indicate that effects on the soil are persistent after 5 years and are presented in the 5-year final pH monitoring report referred to as the White Rain Report (Arcadis 2017a). These results were considered when performing this study and evaluating the results.

The 2008 white rain event slightly changed the conceptual model being tested. The white rain event essentially added a serendipitous treatment component to the study by adding readily available alkalinity before the Amendment Study was implemented. The white rain essentially allowed the study of the effects of liming alone. The white rain applied lime (calcium hydroxide and oxides were in the rain water; Arcadis 2017a) *de facto* on all the plots (including reference plots). This event allows evaluation of the effectiveness of alkaline rain events in increasing pCu and vegetation quality, and provides information on rates of natural attenuation of the adverse effects of copper thereafter.

The Work Plan initially described different lime application rates for each amended plot based on the 2006 pH data, but after the white rain increased pH on all the plots, the application rates were lowered to 1.3 tons per acre (t/ac) as $CaCO_3$ for each of the limed plots (**Table 1**). The white rain did not alter the conceptual model; the hypotheses on the effects of the amendments are as before, but the magnitude of the improvement from the amendments and tilling in pCu is expected to be lower because of the white rain already improving pH and pCu. The effect of the white rain first was tested by evaluating the hypothesis that pH and pCu increased, and plant tissue copper concentrations decreased, after the January 2008 event on both the amendment and reference plots. Any additional effects of the amendments and tilling were then evaluated.

2. Study Design and Description of Remedial Technologies

2.1 Study Design

The Amendment Study was performed on four square 0.25-acre (104 foot x 104 foot) plots (see **Figure 2**) identified as the:

- West amendment plot, representing good to fair rangeland condition (control plot)
- North amendment plot, representing fair rangeland condition
- East amendment plot, representing poor rangeland condition
- Northeast amendment plot, representing fair rangeland condition on steeper slopes.

Plots with different rangeland conditions may respond differently to the remedial technologies depending on their initial rangeland condition. Therefore, rangeland condition was considered when interpreting study results. Baseline rangeland conditions and criteria were determined in 1997 for the STSIU in rangeland polygons (polygon map is included in **Appendix A**) using methods derived by Woodward Clyde (1997). Many decision criteria on vegetation and soil condition were ranked within each polygon as good, fair, and poor (see field datasheets included in **Appendix A**) or ranked to develop an observed apparent trend (OAT) score (**Appendix B-19)**. The observer applied professional judgment across the criteria categories to determine a rangeland condition (good, fair, or poor, or a combination of two if the rangeland falls between classes).

The 1997 ratings were confirmed with later surveys in 2011 or 2014 using the OAT scores. The West plot rating of good-fair was confirmed in the field based on the OAT score for the West reference plot in 2011 ($\geq$ 22 OAT score is considered good-fair, see Arcadis 2011a). In 2014, an OAT score was also assigned to the East reference plot that confirmed its 1997 rating. The OAT score ratings in 2011 and 2014 were conducted with participation by NMED as part of field work for FS studies (2011 and 2014 OAT score sheets are included in the phytotoxicity report, Arcadis 2017b). The North and Northeast plots were not assigned field OAT scores in these later years, and instead were confirmed using a remote-sensing based map of “poor” and “good-fair” ratings that were based on the OAT score (if < 22, “poor”, if ≥ 22, “fair-good”). This predictive map (84% accuracy), developed for the FS, assigns both areas a “fair-good” condition, which confirms that the 1997 ratings are appropriate to characterize baseline rangeland conditions (before treatment).

Each of the four plots, including the West control plot, had an adjacent reference plot that was not treated (see **Figure 2**). These reference plots provide comparison data on the natural recovery of the soil and plant communities in areas with high copper content. The pCu values in the reference plots and other upland areas are predicted to improve naturally over time due to the cessation of the Hurley Smelter operations in 2002 and occurrence of the white rain event, though they are expected to improve more slowly than in the amended plots. The amendment plots and corresponding reference plots were located in areas with higher copper levels averaging between 1,100 and 4,800 mg/kg. Except for the West plots, these areas also exhibited low pCu (< 5) before the white rain event (**Table 1**).

Two or more of the three active remedial technologies of lime, organic matter, and tilling were applied to three of the four amendment plots, with the treatment protocol differing for each plot (**Table 1**). The most efficient way (in terms of cost-benefit) to address the hypotheses for this type of pilot study is to use sampling times as replicates with one control and one impact site sampled at the same time, with each sampling time represented as the difference between the impact and control (Stewart-Oaten et al. 1986). This allowed for the study to be efficient for a small, exploratory pilot study and to try the experiment on a small scale, given the initial limited knowledge on how the ecosystem would respond and given lack of information on which factors would be most variable and require the most replication.

Three plots were amended with lime and organic matter (North, East, and Northeast, see **Table 1**). Lime was applied in the same amount on the three plots, but organic matter was applied at three rates, with the highest (72 t/ac) in the Northeast plot, the next highest (47 t/ac) on the East plot, and the lowest (24 t/ac) on the North plot. Only two plots were additionally tilled: the North and East plots. The Northeast amendment plot was on a steep slope and was not tilled. The East amendment plot, representing poor rangeland condition, and the North plot, representing fair rangeland condition, were on flatter ground and could be tilled. Note that this study tested three rates of organic matter application but did not test the effect of not adding organic matter after liming and tilling.

The plot locations were shifted to a nearby location in some cases before application of the amendments. Two of the four amendment plots (North and Northeast) and their associated reference plots were moved just before amendment application (new location called “post-amendment plots” on **Figure 2**). This was due to the need for a more level surface to bring in equipment for amendment application (Northeast location) and to avoid excessive erosion (North location, see **Table 1**). The new locations were near the original locations. The data obtained from the plots before the move still were used to provide insight into baseline conditions before amendment application in these two general areas.

Reference plot locations close to the amendment plots were selected based upon similar species composition, topography, and soil type. These reference plots initially were used for vegetation sampling from 2008 to 2009, with sampling conducted on one 0.01 ha circular vegetation subplot within each 0.25-acre plot. No soil sampling for lab analysis was conducted on reference plots during those early years. However, soil pH was sampled using field paste pH methods in the 0.25-acre reference plots as well as in the adjacent amendment plot areas in May or early June 2008 after discovering elevated pH as a result of the white rain. These data were used in the statistical analyses requiring “before amendment” pH on reference areas (**Appendix C-1**) and in graphs showing pH trends. From 2010 through 2013, the reference plot sampling area was within the 0.25-acre square plots (of the same size and shape as amendment plots) and sampled for more extensive soil chemistry beyond pH in the same manner as the amendment plots. When copper concentrations were required for “before amendment” on reference areas for statistical analyses, data from the closest plot in the general vicinity of the reference plot sampled as part of the AOC background report (Chino 1995) or STSIU Remedial Investigation Report (SRK 2008) were used (**Appendix C-2**).

2.2 Description of Remedial Technologies

Lime

The white rain event reduced the large differences in pH among the three plots planned for treatment; therefore, the same amount of lime was applied at each of the three amendment plots, and the effects of only one application rate were monitored during this study as described in **Section 1.3**. The lime application rate was based on the soil chemistry documented in May 2008 following the white rain event (see **Table 1**), with a target of maintaining a more alkaline pH of at least 5.5 to 6.5. In 2006, the pH of the amendment plots to be treated ranged from 3.7 (North amendment plot) to 5.4 (Northeast amendment plot). After the white rain in 2008, just before amendment application, pH ranged from 5.7 (Northeast and East amendment plots) to 6.6 (North amendment plot).

The increase in pH between 2006 and 2008 was due to the alkaline deposition in the January 2008 white rain, which distributed calcium oxide and hydroxides (e.g., lime) across the area. Due to the relatively high pH values on the North, Northeast, and East amendment plots in 2008, the same lime application rate of 1.3 (t/ac) was used at three amendment plots. The application rate was consistent with guidance from the New Mexico State University (NMSU) Cooperative Extension Service (CES), which suggested an application rate of 1.5 to 2.0 t/ac for each pH unit increase. Due to its very high pH (> 8), no lime was added in the West amendment plot, and it became a control plot.

Lime amendments were applied as a slurry (oxide or hydroxide) using a modified water truck and a broadcast sprayer. In rough terrain, manual spraying was implemented when necessary.

Organic Matter

Manure from a nearby cattle farm was spread after lime application using a 966 backhoe loader (driving on plot), or manually when necessary. Application rates for the organic matter were varied to determine which rate would provide the best plant community response. The final rates selected differed from those suggested in the Amendment Study work plan (Arcadis 2010b) because manure chemistry data became available. The final rates were based on the assumption that 20 t/ac of manure will provide 2 percent additional soil organic matter (given that an acre-furrow slice of 6-inch depth weighs about 2,000,000 pounds) and that soils to be treated had approximately 2 to 3 percent soil organic matter (based on 0.7 to 1.07 percent total organic carbon [TOC] measured in 2006, see **Section 6**). The 20 t/ac for each 2 percent added was adjusted upward to 24 t/ac to add a 20 percent safety factor and to ensure that results meet success criteria, given high decomposition and oxidation rates of organic matter in semi-arid areas with warm, sandy soils (Parton et al. 1993). The organic matter in soils generally does not exceed 8 percent (NRCS 2001, 2013); therefore, the initial target soil organic matter percentage range was between 3 and 7 percent, with a target of maintaining the percentage over the long term at 3 percent. To meet this target would require organic matter additions ranging from 24 to about 48 t/ac. It was noted that, however, unlike the other plots, the Northeast plot is on a steeper slope (see **Table 1**) and organic matter additions may partially run off after application (which was observed). Therefore, the Northeast plot organic matter addition rate was increased to 72 t/ac to allow for sufficient organic matter to infiltrate into the soils during natural rain events, offsetting the losses possible with runoff. The East amendment plot was assigned approximately 48 t/ac (actual application was 47 t/ac) because it was of “poor” rangeland condition (see **Table 1**), and the North plot was assigned 24 t/ac.

Organic matter was selected not only because the dissolved organic matter from the manure may bind copper, decreasing copper availability to plants initially (Schnitzer and Kodama 1977), but also because it will enrich the soil, increasing plant productivity. Increased plant productivity forms more stable humus that provides for long-term binding of copper within the root zone of the soils (Pandey et al. 2000), especially at moderate to high pH (Suave et al. 1997). Application of animal manure can sometimes create problems, however, such as being a source of high copper concentrations (if cows receive high amounts of mineral additives; Zhang et al. 2012b); a source of acidity; and containing seeds of weedy annuals, some that can be toxic to livestock when consumed in large amounts. The animal manure was tested and did not exhibit high copper levels (~250 mg/kg, see **Section 6**).

Though ammonium present in the organic matter and released through future ammonification will undergo nitrification and release acidity to the soil, measurable decreases in soil pH through nitrification are most often associated with high application rates of highly soluble inorganic nitrogen fertilizer, such as ammonium nitrate application in larger-scale agricultural operations. The ammonium present in organic matter applied as manure in this study will be released much more slowly, and only a fraction of the ammonium released will undergo nitrification; the remainder will be taken up directly by plants, synthesized by soil heterotrophs, and some will become fixed by soil minerals. The addition of lime in conjunction with the organic matter also provides an additional level of protection from depressed soil pH.

Tilling

When tilling was specified by the Amendment Study, all vegetation was cleared and grubbed within the pilot study areas in May 2008 using a bulldozer and/or excavator. Tilling was subsequently completed using a 140 cm wide tilling blade with teeth to cross-rip the organic material into the soil to a depth no greater than 8 inches bgs. In the East plot, it was not possible to till the soil using standard machinery due to the rocky nature of the soil. Therefore, the plot was ripped rather than tilled. For the purpose of this study, tilling refers to either tilling or ripping of the substrate.

Soil ripping has been shown to be an important component of revegetation success in other areas of the STSIU. The results of the Golf Course – Interim Remedial Action (Arcadis 2014), showed that soil ripping to 2 feet, seeding, and hydromulch following surface removal of a few inches of soil is an effective preparation method for revegetation.

In addition, roads throughout the STSIU were effectively revegetated using ripping with no seeding or other amendments. It follows that tilling or ripping of site areas exhibiting sufficient equipment access and appropriate terrain slopes may be a viable remedial technology. To evaluate the effect of tilling or ripping alone, which was not directly assessed on the amendment plots (though it was statistically evaluated by comparing tilled and untilled plots), photographs and site observations of the reclaimed haul roads ripped to 12 to 18 inches deep were reviewed and compared to results from amendment plots that were tilled and amended, as described in **Appendix B-21** (see Photos No. 6 and 7 for September 2014 in **Appendix D** and closeups of vegetation in **Appendix B-21**).

2.3 Best Management Practices

Two best management practices (BMPs) were used to reduce erosion on the amendment plots. Silt fencing was used around the perimeter of all four plots. A wattle was also used in the middle of the North amendment plot to further maintain soil stability. Seeding of the disturbed areas was initially considered as a third potential BMP if 70 percent of the average percent native cover of adjacent reference sites was not achieved before the second rainy season following implementation. However, by October 2009, the average native cover on the amendment plots exceeded 70 percent of the reference plots (Arcadis 2011b); therefore, a native seed mix was not applied.

3. Success Criteria

Success of each remedial technology was evaluated using the following criteria associated with the primary metrics measured for success, which were pCu, plant copper uptake, plant richness, plant cover, and plant community composition:

3.1 Sustained Increase in pCu

In this study, pCu was used as a measure of plant-available copper in the soil. A statistically significant and sustained increase in pCu to greater than 5.0 was preliminarily established as the success criterion because the pre-FS RAC for acceptable soil pCu is $\geq$ 5.0 in areas with copper concentrations exceeding 327 mg/kg (NMED 2011). This success criterion could change after reviewing results of studies completed to inform the FS after the criterion was set (Arcadis 2017a, Arcadis 2017b). Statistical significance of a difference (hereafter referred to as a significant difference) is defined as $P < 0.05$ for all analyses with $n > 6$ for a statistic, and at $P < 0.10$ for a few tests with smaller sample size because of low power (given variability in the samples) to detect differences.

Note that another measure of copper availability was evaluated to improve understanding of mechanisms and interpret results, but is not a primary metric for measuring success, and is considered a “supporting” metric. Specifically, copper leachability within the top 6 inches of soil, as a measure of copper solubility in water, was compared to pre-amendment baseline conditions and adjacent untreated reference plots as another indicator to evaluate success. Synthetic precipitation leaching procedure (SPLP) evaluates the potential mobility of copper from soils upon contact with natural precipitation. If soluble copper by SPLP (referred to herein as soluble copper) is not significantly reduced by the treatments or relative to the adjacent reference plots, the treatments might be considered unsuccessful.

Soluble copper was evaluated because the Site-wide ERA identified it as correlated to plant toxicity endpoints, but it was not as strongly correlated as pCu (Newfields 2005). This is expected considering that soluble copper includes complexed copper species, such as dissolved organic carbon complexes. Such complexes are not taken up by plants (Sauve et al. 1997), and if the addition of organic matter increased these complexes, soluble copper may not decrease. A potential lack of success with respect to this parameter, therefore, must be evaluated in this context and, for this reason, is just a supporting metric, not a primary metric key to determining success of the technology.

Lime was intended to increase soil pH, which should then increase pCu and improve conditions for plant survival and growth. Thus, pH was also evaluated for success as a supporting, rather than primary, metric by determining if the target pH of greater than or equal to 5.5 was achieved and then sustained over the 5-year monitoring period. Initially, an upper bound of pH of 6.5 was provided as a guideline in the approved Work Plan. However, the upper bound is inappropriate because plant communities have adapted to higher pH soils typical of New Mexico (e.g., 6.5 to 8.0; Flynn 2012, see discussion in Arcadis 2013), and these higher pH values (greater than 6.5 s.u.) potentially can be beneficial and further reduce availability of copper to plants (e.g., Elbana and Selim 2011).

Similarly, the lower bound pH of 5.5 is a general guideline, and most important to achieve in soils with high copper, and is less important in soils with low copper (e.g., less than 327 mg/kg as defined by the pre-FS RAC). Thus, pH is a supporting metric because ultimately, plants are responding to the combination of copper and pH, quantified as pCu, rather than pH alone. Similarly, net neutralization potential, measured as part of acid base accounting (ABA), supported interpretations of the observed persistence of pH increases.

3.2 Reduction of Copper in Plant Tissue

A reduction in uptake and translocation of copper into leaf and stem tissue was evaluated by sampling plant tissue to directly assess effects on the plant of the change in bioavailability of copper (as measured by pCu). Success is indicated by a statistically significant reduction in copper in plant tissues following amendments and relative to reference plots. For this report, uptake of copper is defined as uptake of copper into the aboveground stems, leaves, and reproductive parts of the plant.

3.3 Increased Plant Cover and Richness and Improved Community Composition

The percent cover and species richness (number of species) of the plant community present in amendment plots after 5 years were compared to data collected before amendment/tilling treatments and from adjacent reference sites. Success is considered an increase in these parameters 5 years after treatment and compared to reference plots (unlike pCu, the increase is not expected 1 year after treatment because it takes time for plant communities to respond to soil chemistry changes). Success is also measured by a change in the community composition that improves wildlife habitat and livestock range.

The supporting metrics for evaluating community composition included Shannon diversity and Shannon evenness (Gotelli and Chao 2013). Shannon evenness is a measure of the relative proportions of each species, with even proportions indicating lack of dominance by any one species. Shannon Diversity combines evenness and richness to develop an index to overall diversity.

Other soil variables evaluated as supporting metrics that influence plant communities were TOC and carbon:nitrogen (C:N) ratio. The ideal target for good community development following the treatment disturbance is an organic matter content of at least 3 percent, equivalent to approximately 1% TOC (Konare et al. 2010) and a C:N ratio between 8:1 to 15:1 (Ward Laboratories 2014). However, as long as C:N is less than 20:1, a ratio below which NH_4^+ becomes available to plants through nitrogen mineralization (Whalen and Sampredo 2010), the soil metric was considered acceptable and met the remedial objective. C:N ratios below 8:1 result in volatilization and loss of nitrogen, which is less than ideal, and may hinder community development. The 3 percent organic matter target is an intermediate level of organic matter believed to be achievable in sandy soils.

Other nutrient concentrations were evaluated as supporting metrics to help interpret the primary metric results including nitrate/nitrite, ammonia, total Kjeldahl nitrogen (TKN), and total calcium and potassium.

3.4 Vegetation Establishment Success Guidelines

Before assessing the primary or secondary metrics, the treated plots must first meet vegetation establishment success criteria to show that native communities re-establish. In other words, if predominately native vegetative communities cannot re-establish after amendment/tilling, remediating to reduce phytotoxicity is counter-productive because the disturbance would have caused a greater reduction in services than the reduction in copper bioavailability.

Short-term (2-year) and longer-term (5-year) success criteria were established to evaluate vegetation establishment after disturbance from amendment and tilling activities (Arcadis 2011b). The criterion for the short-term goal of vegetation re-establishment was defined as native vegetation cover greater than 70 percent of the native cover of adjacent reference plots (Arcadis 2008) before the end of the second rainy season. The goal of the short-term criterion was to provide a benchmark for the amount of cover needed to limit problems associated with soil erosion and from not seeding.

In general terms, the longer-term 5-year success criteria for vegetation re-establishment include:

- Colonization of a diversity of native species important to a native plant community typical of the region, where important species are defined as perennial grasses and forbs of high quality for livestock and wildlife
- Development of horizontal and vertical complexity (heterogeneity) important to wildlife habitat (i.e., development of multiple vegetative strata including shrubs)
- Low proportion of exotic/invasive plant species characteristic of areas of natural and/or anthropogenic disturbance
- Increasing total vegetation percent cover and decreasing total percent cover of bare soil.

NMED requested that the success criteria from the Closure/Closeout Plan (CCP) reclamation guidelines based on the Tailings Reference Area just west of Tailing Pond 7 be used as the specific, quantitative, long-term criteria for the Amendment Study after 5 years. Those criteria were developed for a 12-year-old restored plant community (Daniel B. Stephens & Associates, Inc. 1999 and Chino 2007). Therefore, not all of these criteria may be met in the 5 years during which the vegetation community was evaluated. The CCP requirements are provided in **Table 3**.

4. Monitoring Activities

The following section provides an overview of the Amendment Study monitoring activities including the monitoring approach, BMP inspection, and soil and vegetation sampling and analysis.

4.1 Overview and Work Plan Modifications

As discussed previously, the monitoring approach described in the Work Plan evolved over time. Additionally, statistical power analyses conducted after 3 years of sampling (described in Arcadis 2012) led to increasing sample sizes for surface soils for years 4 and 5. The monitoring approach included the following tasks:

- **Establish and Monitor Baseline Conditions:** Baseline soil conditions were established and monitored with lab analyses of the soil at the four amendment plots. Baseline conditions at the reference plots were established in March 2008 (see **Table 1,** copper was not sampled in 2006 but was sampled in 2008). Vegetation baseline conditions were established on the four amendment plots in March 2008 by sampling the cover by species, total vegetative cover, and aboveground plant tissue for copper concentrations. These same variables were sampled on the reference plots except for copper concentrations in plant tissue. Soil pH also was sampled in May 2008? or June 2008 on reference plots. Note, the white rain fell between the two (2006, 2008) baseline sampling events.

- **Post-Amendment BMP Inspection:** BMPs were inspected through one rainy season for effectiveness and repair as necessary. Each plot was inspected to assess the integrity and effectiveness of installed BMPs. Inspections were conducted at 2 weeks, 6 weeks, 6 months, and 18 months after amendment implementation.

- **Post-Amendment Soil Sampling and Analysis:** Sampling and analyses of soils was conducted semi-annually for 5 years in the amendment plots and 4 years in the adjacent reference plots (starting in 2010 on reference plots, except pH was also sampled in 2008, see **Table 1**). The exception was ABA, which was conducted once on amendment plots in December 2008 and annually in the fall on adjacent reference plots from 2010 to 2013. Except for pH, reference plots were not sampled before amendment application or in 2008 and 2009 because, unlike vegetation, soil data in reference plots were not part of the success criteria. However, starting in fall 2010, in response to NMED comments on the Year 1 monitoring report (NMED 2010) and recognizing the high variability in soil parameters on the amendment plots, reference plot soils were sampled to evaluate the degree of change caused by temporal and spatial variability unrelated to the amendment application. Measured pCu was sampled only once in October 2013.

- **Post-Amendment Vegetation Sampling and Analysis:** Vegetation was sampled and analyzed in the first (December 2008), second (October 2009), third (April and October 2010), and fifth (October 2013) years following amendment to evaluate community composition and vegetation colonization. The short-term percent cover targets were met during the first monitoring season; therefore, it was agreed that semi-annual or yearly monitoring of vegetation provided little benefit to the overall study. The final vegetation survey was completed during year 5 (fall 2013). This approach is consistent with CCP recommended protocols (Daniel B. Stephens & Associates, Inc. 1999 and Chino 2007), which require sampling in the fall, and provided enough data to assess effectiveness of amendments and tilling in increasing plant cover and richness. Plant tissue was sampled in 2013 at the amendment and reference plots to evaluate concentrations of copper in aboveground biomass.

4.2 Monitoring Soil Conditions

Before implementation of the Amendment Study, baseline soil sampling was conducted within the four amendment plots in July 2006 and May 2008. The 2006 soil sampling was reconnaissance sampling, and thus was not as extensive as sampling conducted in 2008. Baseline sampling was conducted to establish a pre-amendment condition to which subsequent data analyses could be compared. The 2008 baseline soil data allowed for assessment of the effects of the amendments/tilling on soil chemistry rather than white rain, whereas the 2006 soil data compared to the 2008 soil data allowed an assessment of the role of white rain. Post-amendment soil sampling was semi-annual from December 2008 to October 2013 and was more extensive.

4.2.1 Baseline Soil Sampling

Soils were sampled for pH, TOC, nitrogen species, and copper (total and soluble) in 2006 and 2008 to estimate baseline soil conditions prior to the Amendment Study. Within each of the amendment plots in 2006, a soil sample was collected at a single random surface location (**Appendix C-3**), at 0 to 4 inches or 0 to 5 inches bgs (the East plot with windblown tailings on the surface was further split into 0 to1 inch and 2 to 4 inch strata). In 2008, about 1 month before application of the amendment, the number of random samples was increased to two samples per plot and two depth strata in order to better capture soil heterogeneity. At each sample location in 2008, soil was collected from the surface (a depth of 0 to 6 inches) and subsurface (targeted 18 to 24 inches if possible).

The shallow surface sampling specifically focused on soil within the target mixing zone (i.e., top 75 percent of the tilling zone), whereas the deeper sampling was intended to monitor for the potential downward migration of amendments through the soil column over time and show whether copper or acidity have changed over time with depth in the lime-treated plots, indicating some migration of hydrogen or cupric ions after treatment. A hard pan clay layer underlies the soil throughout the study areas, and the depth of deeper samples was adjusted accordingly. Specifically, the deeper samples were collected in the lowest 6 inches of the deep stratum (if clay hard pan was present, from top of clay hard pan layer upward for 6 inches). The hard pan clay layer was too difficult to penetrate during soil sampling, and the depth of the subsurface samples was selected based on the assumption that leaching does not occur below this clay hard pan layer. Actual sample depths for subsurface samples collected from 2008 to 2013 are provided in **Appendix C-4**.

4.2.2 Post-Amendment Soil Sampling

Following amendment application, from December 2008 to 2011, two or three soil samples were collected at each amendment and reference plot at depths of 0 to 6 inches (**Appendix C-3**) and 18 to 24 inches (adjusted depending on clay hard pan layer depth), as detailed above for baseline soil sampling (see **Appendix C-4, C-5** for subsurface data). Random (rather than permanent) sample locations were established to evaluate the changes in the soil concentrations throughout the study area and capture spatial variability. However, variability was found to be high, and sample size was increased from two or three up to eight samples to estimate total copper, soluble copper, pH, and pCu in surface soils in 2012 and 2013 to increase the statistical power to detect significant differences (see Arcadis 2013 and **Section 7.2**). Sampling protocols established for subsurface soil and other parameters for surface soil were not changed.

4.2.3 Soil Analytical Methods

Soil samples collected for the Amendment Study were subjected to the testing program detailed below. Samples were air-dried at 34 degrees Celsius before analysis, and all estimates were based on dry weight.

Total Copper: Total copper in soil was determined by subjecting samples to acid digestion using U.S. Environmental Protection Agency (EPA) 3050B followed by inductively coupled plasma-atomic emission spectroscopy (ICP-AES) analysis (EPA 6010B) with a method detection limit of 1 mg/kg.

Soil pH: Soil pH was analyzed using deionized water at a 1:1 soil to solution ratio (EPA 9045C) or saturated paste.

Soluble Copper: Soluble copper was determined by modified SPLP (EPA 1312) using a 5:1 ratio with $CaCl_2$ extraction fluid without pH adjustment. The method was inadvertently switched to the standard SPLP method, which is based on a 20:1 water to sample ratio, using deionized water adjusted to pH 5, when laboratories were switched from SVL Analytical (Kellogg, Idaho) to ACZ Laboratories (Steamboat Springs, Colorado) from fall 2011 through spring 2013. Samples collected in fall 2013 were subjected to both methods. Comparison of results (see **Section 6**) showed that a scaling factor was not appropriate; therefore, the associated statistical analyses were based on the soluble copper by the modified 5:1 ratio method (20:1 ratio samples were dropped from the analyses).

Nutrients: The nutrient analyses included nitrogen speciation (nitrate/nitrite as N-soluble [EPA 3533.2], ammonia as N [EPA 350.1], TKN [SM 4500]), TOC by EPA 9060 or ASA No. 9 29-2.2.4, and calculated C:N).

ABA: Soils subjected to ABA were sieved to less than 250 microns (µm) following standard procedures. The ABA included measurement of neutralization potential and sulfur forms (total sulfur, pyritic/sulfide sulfur, sulfate sulfur, and organic/insoluble sulfur) using the Modified Sobek procedure (EPA M600/2-78-054), specifically:

- Neutralization potential in percent as calcium carbonate ($CaCO_3$) was determined using EPA M600/2-78-054 3.2.3, with a 0.1 percent method detection limit. The laboratory calculated acid neutralization potential (ANP) in t $CaCO_3$ per kiloton (t $CaCO_3$/kt) by multiplying the neutralization potential by 10.

- Sulfur forms (total, pyritic/sulfide sulfur, sulfate sulfur, and organic/insoluble sulfur) were determined using EPA M600/2-78-054 3.2.4 with a 0.01 percent detection limit. Total sulfur content was determined by combustion via Leco furnace. Sulfur forms were analyzed on separate sample aliquots, with a subsampling digested in hydrochloric acid (HCl) and another digested in nitric acid (HNO_3). The term pyritic sulfur (or pyritic/sulfide sulfur) is used; however, this methodology does not distinguish between pyritic (FeS_2) and non-pyritic sulfide minerals (e.g., CuS).

- The acid generation potential (AGP) in t $CaCO_3$/kt was calculated by the laboratories or Arcadis by multiplying the sulfide sulfur content (reported as pyritic sulfur by SVL and pyritic/sulfide sulfur by ACZ laboratories) in percent by a conversion factor of 31.25, based on acidity generated by pyrite oxidation (assuming all sulfide sulfur oxidation is represented by pyrite oxidation).

ABA results were used to determine the neutralization potential ratio (NPR = ANP/AGP) and net neutralization potential (NNP), where NNP is the difference between the ANP and AGP (i.e., NNP = ANP - AGP). These criteria are commonly used to categorize material into potentially acid-generating (PAG) or non-potentially acid-generating (non-PAG). Numerous interpretation schemes have been developed to assess the potential for acid generation using either criterion. For example, a sample with an NPR less than 1.0 will typically be characterized as PAG, whereas an NPR greater than 2.0 represents a non-PAG sample (i.e., at least twice as much ANP as AGP). A sample with NPR values between these designations is considered to exhibit uncertain acid-generating characteristics (Arcadis 2017a). The New Mexico Mining and Minerals Division (MMD) soil and overburden suitability guidelines, which are directly applicable, rate soil material as good based on an NNP of -5 t $CaCO_3$/kt or greater and unacceptable based on an NNP of less than -5 t $CaCO_3$/kt (MMD 1996).

Measured pCu: The Cu^{2+} activity in soil, reported as pCu, was measured only in October 2013 using a calibrated Cu^{2+} Ion-Selective Electrode (Cu-ISE) as detailed in Arcadis 2014. The Cu-ISE was calibrated in an aqueous solution containing a specified concentration of dissolved Cu and adjusted to a variety of pH values to produce a corresponding variety of pCu values. The resulting pCu calibration curves were used to calculate the pCu of soil extracts from the Cu-ISE millivolt (mV) readings (**Appendix C-6**).

Calculated pCu: pCu data reported herein are calculated from total copper concentration and pH unless specified otherwise (as measured). The equation used to determine calculated pCu values is discussed and presented in **Section 1.2**.

Additional Analyses: Total calcium and potassium were determined by acid digestion using EPA 3050B followed by ICP-AES analysis (EPA 6010B).

The approved Work Plan (Arcadis 2008) did not require the soil samples to be sieved before analysis. Soils collected from the Amendment Study areas were not sieved in 2006, 2008, 2009, or 2010. However, the Pre-FS RAC (NMED 2011) data are based on sieved samples, and thus, the FS will use results from sieved soil. For consistency with the FS, soils were sieved for copper and pH analysis to less than 2 mm in spring and fall 2011 and 2012. Regression equations displaying a strong, significant relationship between sieved and unsieved soils were developed by analyzing sieved and unsieved soils for pH and copper in spring 2011 (Arcadis 2012). Equations were:

- $pH_{sieved} = 1.2424pH_{unsieved} - 1.8933$, $r^2 = 0.82$, $P < 0.001$;
- $Cu_{sieved} = 1.0341Cu_{unsieved}+233.13$, $r^2 = 0.86$, $P < 0.001$

Unsieved soils tend to exhibit lower copper concentrations and higher pH, though estimates did not show large changes (see Arcadis 2012 comparison). All pH and copper measured in years for which soils were not sieved were adjusted to estimate sieved values using the regression equation. The results in the tables and text of this report are based on sieved or estimated sieved values.

4.2.4 Statistical Analysis of Soil Data

Effect of Amendments and Tilling. This section provides an overview of the statistical Before-After-Control-Impact (BACI) design used to evaluate whether significant changes from the amendments/tilling were observed in the soil during the Amendment Study. McDonald et al. (2000), Smith (2002), and Schwarz (2015) explain the BACI method and provide other references. The BACI design examines the Before (pre-amendment baseline) and After (post-amendment) conditions of the area, as well as comparing a Control (reference site) with the Impact site (remediation site). The pre-amendment conditions in this analysis exclude conditions before the white rain so that the effectiveness of the amendment/tilling alone can be evaluated.

Before and After sampling determines how the remediation process changed the Site through time from its trajectory had the treatments not been applied. Control and Impact sampling will identify if the change occurring ostensibly from the remediation (impact site) also occurred in the untreated reference site (control site), and thus was not from the remediation. The BACI design allows discernment of effects of remedial actions from natural variability and underlying trends in the larger area. For example, BACI data analysis can compare pre- and post-amendment pH and provide confidence that a difference in pre- and post-amendment pH is due to the amendment activity rather than a regional or locational effect that is changing both the reference and amended plot in the same direction.

Figure 3 illustrates how BACI data are compared to detect if there is a significant change in the mean of a parameter immediately after the impact relative to a control plot (e.g., if significant interaction term in a two-way analysis of variance [ANOVA]). The BACI analysis was conducted on pH, total copper, and pCu. Data on reference plots or similar nearby areas were unavailable for the pre-amendment period for the other soil constituents (soluble copper, TOC, C:N).

The “impacts” tested in this BACI analysis were: (1) lime and organic matter application, which should increase pH and pCu, and (2) “tilling,” which should decrease total copper and increase pH and pCu by mixing the copper and lime in the top 6 inches of soil with lower subsurface soil (designed to assist plant establishment). The BACI only evaluates the change in means in two periods (the before and after periods), not persistence of the initial impact (treatment).

Mixed model ANOVAs were used for the BACI analysis. A mixed model ANOVA evaluating differences in means of soil parameters includes “fixed” factors and “random” factors, where a factor is a categorical variable. Fixed factors of plot type (amendment or reference plot) and period (before, after) are the focus of the investigation. Fixed factors test two main effects to evaluate amendment (lime, organic matter) effectiveness: Main Effect 1, which compares means of amendment plots vs. reference plots, and Main Effect 2, which compares means of the pre-amendment period vs. post-amendment period. Most importantly, the interaction of these two fixed factors is tested (amendment vs. reference x pre-amendment vs. post-amendment) to determine if the treated plots respond differently between the pre- and post-treatment period than the untreated plots.

If the interaction is statistically significant ($P < 0.05$), then the treatment had an effect. To evaluate tilling, the same factors are investigated, except the Main Effect 1 compares tilled plots to all untilled plots[7]. The Main effect 1 and 2 of the ANOVA may or may not be significant, but their significance is not important to the interpretation of the results. For example, if both the reference and amendment plots significantly increase pCu after amendment application, the increase cannot be presumed to be from the amendment unless the amendment plot increased more than the reference plot (see **Figure 3**). This

---

[7] Untilled plots include untreated plots and plots amended but not tilled.

larger increase would be demonstrated by a significant interaction term and different magnitude of change in the means in the ANOVA results.

Random factors influence the comparisons and must be included but are nuisance factors measured on a subset of units from a larger population of units in the area. For example, the four plot locations are selected from a very large population of possible plot locations on the STSIU. Ideally, the locations should be randomly selected or at least representative of the larger population, but the model is fairly robust to deviations from the ideal. The model assumes that selected plots are representative of the main habitats in the STSIU. Though there is uncertainty in that assumption, it was believed to be reasonable.

Results also can be strongly influenced by the characteristics of the habitat at the plot location (slope, rangeland condition, geology) regardless of treatments. Plot location (North, West, East, Northeast) is included as a random factor (nuisance variable) that must be taken into account to assess the effect of the treatment. Sampling event (season, year) is also a random factor nested within the larger pre- and post-amendment periods. The sampling events in the model are a subset of many possible sampling events over the years, and should be representative of the time period of interest (fall or spring season of each year during study), which they mostly are—spaced every half year with some exceptions (they are systematically spaced over time to capture the characteristics of the period).

The pre-amendment period is very short but represents an interval in time (half year) similar to the the post-period units[8]. A random factor interaction term (multiplying plot location by sampling date nested within period) was included in the model because interactions are possible between plot and sampling event. The least square means for the four categories of the main effects (e.g., pre-amendment amendment plot, post-amendment amendment plot, pre-amendment reference plot, post-amendment reference plot) are the ANOVA means, which are simply the soil means at each plot location within a sampling date averaged across these four categories. Each mean is given equal weight (not weighted by sample size when averaged) when calculating the

---

[8] 2006 originally was planned to be part of the baseline but when the white rain event happened, it could no longer be included because it would represent effects before both the white rain and treatments, not just the treatments.

least square mean to prevent any biases toward a plot location or date that had a higher sample size in the analysis.

As shown in **Table 1**, soil data for copper and pCu collected following the Work Plan for the pre-amendment period were not collected on the adjacent reference plots until 2010, which could have prevented the use of the BACI design for the Amendment Study for all but pH due to the lack of available data on reference plots before amendment application. For pH, data were available for the BACI because 5 months after the white rain in May 2008, field soil paste pH in 0 to 6 inch depth soil was sampled in the reference and amendment plots before the amendment application in June 2008. These pH data were used as pre-amendment pH data for the BACI. Ten surface soil samples (0 to 6 inches), each from the amendment and reference plots, were analyzed using field paste pH methods for each location (80 samples total, see **Appendix C-1**). These data were collected to better understand the large increase in pH observed, which was later determined to be from the white rain.

Two additional 0 to 6 inch samples on the amendment plots were sent to the laboratory for pH analysis on the North, Northeast, and East plots in accordance with the Work Plan (results in **Table 4** and **Appendix C-3**). For those three plots, the results using field paste pH methods combined with laboratory samples were not significantly different from laboratory soil pH data collected in the same plots during the same sampling event (two-way ANOVA with factors of plot and method, $P = 0.294$, data shown in **Table 4**). Therefore, the combined pH field and laboratory data in 2008 were deemed adequate for evaluation of white rain effects and for the BACI analysis.

To fill the data gap for copper data (and pCu, which is calculated from copper data) missing on adjacent reference plots before treatment, copper concentrations in soil collected in areas near the amendment plots in the 1990s and early 2000s (reported in other reports) were used. These data often are less collocated spatially with the amendment plots than the data collected on the reference plots. Data collected on the adjacent reference plots that were part of the study design are referred to herein as “collocated” with the amendment plots because they were collected at a short distance of 272 feet or less from the treated plots (**Figure 2**). The newly added locations are referred to as “less collocated” data to fill the data gap. The less collocated data were collected within 1,130 feet, recognizing that some were much closer (one at 139 feet distance; most were within 660 feet, shown on maps in **Appendix C-2, Figure C-2-1 and C-2-2**). The less collocated copper data came from the STSIU RI report (SRK 2008), sitewide ERA (Newfields 2005), and AOC background report (Chino 1995).

With one exception, the less collocated plots are in the same geologic unit (**Figure C-2-1 in Appendix C-2**) and soil category (**Figure C-2-2**)[9] as their nearby amendment plots, and thus are likely representative of the nearby amendment plots. The one exception was the less collocated plot U04-1037 used for the North amendment plot's reference, which was on an ash-flow tuff (Trt) rather than a rhyolite-based fan deposit (Qfr) and a relatively flat rocky type rather than relatively flat granular soil type. However, pH from this plot (and other less collocated plots) was not used, just its total copper concentration (for pH, the adjacent collocated plot's pH was used).

Total copper on average probably would not change much whether deposited by the smelter on ash-flow tuff rocky soils or rhyolite-based, more granular soils. As long as its distance from smelter is similar to that of the amendment plots, even this plot should not represent a copper concentration biased high or low. The greater issue is the high variability in copper within and among locations, as discussed below.

The less collocated copper data are reported in **Appendix C-2**[10] and were treated as pre-amendment reference copper data to complete a BACI analysis for total copper and pCu. In addition to their spatial proximity, these data were deemed acceptable because copper concentrations, though variable due to spatial heterogeneity of the soil, have not changed greatly over this time period (1995 to 2004, see Arcadis 2017a). The less collocated copper data and calculated pCu data (calculated in **Appendix C-2** using the collocated pH with the less collocated copper data) are shown on **Figures 4a** and **Figure 4b**, but are not connected by a line to the other data because they are estimates. These reference data are included to better approximate the variability and trend in pCu from events unrelated to amendment and tilling, including mine operation changes, changing laboratory conditions, long-term effects from the white rain, and variable climatic effects. Smokorowski and Randall (2017) discuss the advantages of BACI analyses, if designed correctly, over suboptimal designs without reference data, and they discuss uncertainty around poorly designed BACIs. Using different reference plots in early years from those in later years creates uncertainty, however, because copper differences may be due to inherent differences in the copper concentrations of the different reference plots, rather

---

[9] Soil categories are defined in the phytotoxicity study (Arcadis 2017b) as: bedrock, slope, flat granular, and flat rocky soils (see map in **Appendix C-2-2**).

[10] After copper data were standardized to 0-6 inch depth and 2 mm sieve, as shown in Appendix E of the white rain report (Arcadis 2017a).

than representing trends in untreated plots over the early year period (prior to 2010). Consequently, copper and pCu statistical comparisons without the less collocated plots were also conducted. Specifically, the means of these two constituents were compared across space and then time.

For the comparison across space, collocated reference plot estimates, averaged over the post-treatment period of 2010 to 2013, were compared to amended plot averages for the same period for the following constituents: pH, copper, pCu, soluble copper, TOC, and the C:N ratio. This analysis was conducted for each individual plot location, and provided supporting information for copper and pCu that does not rely on less collocated data (the other four constituents never relied on less collocated data). For this comparison across space, ANOVAs were run separately on each of the four locations (North, West, East, Northeast), and year was included as a blocking factor to avoid biasing results toward years with more samples.

If the reference plots had the same average values as amendment plots before treatment, improved values after treatment on the amended plots would indicate remedy effectiveness. However, this approach assumes that copper and pCu averaged the same values in the amendment and reference plots before treatments were applied, which was unlikely because pH was different between the two plots before treatment (**Appendix C-1**). Therefore, a second comparison (a comparison in time) was conducted without the less collocated plots or any reference plot data. Pre- and post-treatment period means were compared for copper and pCu on the amendment plots. Results are presented in the Alternative Analyses in **Section 7.2.2**, and all analyses of pCu and copper compared to identify the uncertainty in the results. Overall, the alternate analyses for copper and pCu did not change conclusions obtained from the BACI.

A BACI analysis could not be completed for soluble copper, C:N, or TOC because reference data before amendment application were unavailable. Not being primary metrics, these are less critical for interpreting trends over time than pCu; hence, the other methods of analysis, comparing effects in space and time separately, were employed for these. Evaluations were conducted with: (1) ANOVAs for each location comparing soil means of reference and amended plots averaged over the 2010 to 2013 period as discussed above and (2) mixed model ANOVAs comparing amendment plot means in May 2008 before a particular treatment (lime and organic matter, till) and afterward for one or two sampling events with no reference plots included. For the second comparison across time, all locations were included in one ANOVA, and plot location was included as a random variable. For TOC and C:N, 2006 data were available, and thus the pre-amendment period for the comparison in time was the mean for two sampling events

(July 2006 and May 2008) based on the assumption that the white rain between these periods likely did not impact these soil variables. Also, because changes from the added organic matter appeared to be slow to incorporate into the soil, TOC and C:N were evaluated for two sampling events after amendment application (after 6 months and 1.5 years).

Because the BACI design does not evaluate persistence of the effect of the treatment (only compares means of before and after period), a separate persistence analysis was conducted on the 5 years of data collected after amendment application. This analysis evaluates if the slope of the linear regression in a parameter (e.g., pH) over time was not significantly different from zero, meaning the value of the parameter in each post-amendment sampling event has remained relatively constant over time (can fluctuate but is not increasing or decreasing) and thus is persistent. If the BACI analysis supported that the amendment caused the initial change predicted for the parameter (e.g., initial increase in pCu) and then the linear regression shows that the parameter remained constant for 5 years, one might conclude that the hypothesis of the predicted change being sustained for 5 years was supported. However, the reference plot may show a different trend in the soil over the 5 years (e.g., increase in pCu rather than constant pCu), which brings into question why the reference plot changed or improved over time and the treated plot did not under the same climatic conditions. If the reference plot improved in pCu over time, and the pCu of the treated plot remained constant after the initial increase, resulting in the same pCu for both plots at the end of 5 years, the treatment provided no long-term benefit and was not successful. Therefore, to evaluate if the treatments are beneficial, the “difference in soil chemistry” plotted over time between an amendment plot and its adjacent reference plot fitted to a regression line was used to identify whether persistence was beneficial relative to the reference plot. If the initial difference between the reference and amended plot resulting from treatment remains constant over time, and the slope of the regression fit to the difference data are not significantly different from zero, the effect of the remediation was considered persistent and beneficial (a success). If the difference decreases to zero after 5 years, the amendment improvement was not beneficial. In other words, the difference between the plots from the amendments and/or tilling should be maintained (slope of the difference regression not significantly different from zero) if the effect is persistent and beneficial.

Effect of the White Rain. White rain effects were not evaluated with a BACI because no reference plots existed that were not exposed to white rain. To evaluate the effect of the white rain, a blocked ANOVA comparing pre-white rain data (2006) to post-white rain data (May/June 2008) on amendment plots was conducted, where the four plot locations were the blocks. To support the validity of the analysis, the magnitude of the white rain effect on pH, copper, and pCu was compared to the magnitude identified for the STSU in the white rain report (Arcadis 2017a) for ERA plots with pH < 5.5. Plots with such levels of pH exhibited low buffering capacity and responded to the white rain, whereas plots with higher pH did not.

Effect of Organic Matter Alone. The effect of organic matter additions applied at three different rates could only be evaluated qualitatively with considerable uncertainty because of too many confounding factors (different rangeland condition, slope, tilling treatments). These factors cannot be separated in statistical analyses given the small sample size (only three plots received the organic matter). Lime effects evaluated included organic matter because organic matter was always applied with the lime. Large changes in pH, however, were predicted based on the lime, not the organic matter.

Surface versus Subsurface Soils. All analyses discussed above were performed on surface soils of 0 to 6 inches bgs. Surface soil parameters were also compared to those of the subsurface to monitor the downward migration of amendments through the soil column and address concerns that the lime addition will infiltrate downward beyond the shallow soil zone with precipitation and would not be effective at increasing pH in the shallow soil in the long term. Additionally, the analysis examined whether copper is moving downward and eventually out of the main root zone. To address these questions, the trends in pH and copper concentrations over time in each plot in the surface and subsurface soil were qualitatively evaluated to determine if copper or acidity have changed over time at depth during surface treatments.

Subsurface soil pH and copper also were plotted against surface soil pH and copper in a regression. The regression should exhibit no relationship between surface and subsurface soils in reference plots if high copper and depressed pH from the smelter have not reached the deeper soil layers and in amended plots if the lime and amendments have not impacted the deeper layers after 5 years.

4.3 Monitoring Vegetation Conditions

Vegetation sampling included: (1) sampling plant tissue to analyze copper concentrations and (2) measuring vegetation community parameters. Baseline vegetation sampling within the four amendment plots and adjacent reference plots was conducted in March 2008, a few months before amendment application (**Appendix B**). Post-amendment sampling of community parameters occurred on five occasions that were wet enough to adequately characterize the vegetation, mostly in the fall: December

2008, October 2009, April 2010, October 2010, and October 2013. Plant tissue was sampled before amendment application in March 2008 (only in amendment plots) and post-application in October 2013 (on both amendment and reference plots). Photographs from the fall and spring sampling of the amendment and adjacent reference plots before and after amendment over the 5-year monitoring period are provided in **Appendix D**.

4.3.1 Baseline Vegetation Sampling

In March 2008, during the non-growing season (representing plant uptake during the previous growing season before the white rain), plant tissue samples were collected throughout the amendment plots. Samples included the entire aboveground plant (shoots, leaves, and seeds) and were not washed before lab analysis. During this same sampling period, two permanent 0.01-acre (11-foot radius) vegetation circular subplots were established in each amendment plot and a single 0.01-acre circular subplot was established in the associated reference plot. Each subplot was identified using a 24-inch black steel marker with pink flagging attached. Global positioning system (GPS) coordinates were recorded for each subplot using a hand-held GPS unit.

A professional botanist identified species present within each 0.01-acre circular subplot. The total number of species present per plot was used to estimate species richness (number of species), and species cover per plot was used to calculate Shannon Evenness and Shannon Diversity. Canopy cover midpoints (**Table 5**) were assigned to each species following Daubenmire (1959). Canopy cover summed over all species in a plot can exceed 100 percent due to overlap; therefore, in addition, total vegetation cover and percent bare ground were estimated, which total to 100 percent. Percent of vegetation that was native or composed of annual species was also assessed for each plot. In the original work plan (Arcadis 2008b), shrub cover was also planned to be sampled in a 0.1-acre circular plot (a larger plot may be more accurate for shrubs than a small plot), and was sampled at baseline and in Year 1 of monitoring. However, this plot was removed from future monitoring and all analyses in this report because there was little difference between shrub cover in the small and large plots.

4.3.2 Post- Amendment Vegetation Sampling

In October 2013, plant tissue samples were collected from throughout the amendment plots, as in 2008, and included the entire aboveground plant (shoots, leaves, and seeds). When honey mesquite (*Prosopsis glandulosa*) was collected, 5 percent of the weight was seeds and the rest was foliage. It was estimated that 15 percent of the weight of the whole aboveground tiller for the grasses collected were seeds and the rest was foliage. Copper concentrations were analyzed on washed and unwashed samples of the same species. **Appendix B-1** contains the standard operating procedure (SOP) for collecting seeds and foliage. A regression was then developed (see **Appendix B-2**) to predict washed from unwashed concentrations or vice versa, given that data collected on plants before 2013 were from unwashed samples. Washed results represent actual plant uptake, but unwashed results were used to compare changes in copper concentrations in tissue over time. Unlike the plant tissue collected in 2008, plants were collected during the growing season in 2013.

In five sampling periods, from December 2008 to October 2013, the sampling of the vegetation community parameters conducted at baseline was repeated after application of amendments/tilling using the same methods described for baseline. In addition, to evaluate success of vegetation establishment after disturbance using reclamation criteria, CCP sampling methods were performed in October 2010 and October 2013 as specified in the revised work plan schedule (see Appendix A of the Year 2 report for revised schedule). CCP sampling methods must be used to compare to the CCP reclamation criteria.

The CCP methods outlined in Daniel B. Stephens & Associates, Inc. (1999) and Chino (2007) specify sampling in the fall. These methods were adapted to fit the small size of the amendment plots. Specifically, quadrats were placed on transects to collect percent cover and shrub density data. Each 0.25-acre amendment plot was divided into 25 20-foot by 20-foot blocks, with five blocks randomly sampled in each amendment plot each year. Two 20-foot transects were located in each randomly selected block in a dogleg pattern. The first leg of a transect originated in the southeastern corner of each block. A 3.3-foot by 3.3-foot quadrat (i.e., 1 meter square) was placed at 5 and 15 feet along each transect. CCP sampling was not conducted on the reference plots.

For the CCP sampling, conducted solely for comparing results to CCP success criteria, total canopy cover, species canopy cover (aboveground), basal cover (on ground only), surface litter, surface rock fragments, and bare soil were visually estimated in each quadrat by a professional botanist. Canopy cover estimates included the foliage and foliage interspaces of all individual plants rooted in the quadrat. As with the circular plot sampling method described above, percent cover was estimated on a species basis and totaled greater than 100 percent when summed across all species in individual quadrats because foliage overlaps. In contrast, the sum of the total canopy cover, surface litter, rock fragments, and bare soil does not exceed 100 percent. Species occurrence was determined by traversing the selected block and listing all the species encountered. In addition, the number of individual shrub plants in each quadrat was counted by species to estimate shrub density per square meter quadrat. Finally, the point-centered quarter (PCQ) method (using distance to nearest shrub measurements, see Bonham 1989) was used at each quadrat location to estimate woody plant density. The terminal nodes of the dogleg transects were used as the fixed points for the PCQ distance measurements.

4.3.3 Vegetation Analytical Methods

Plant tissue samples collected in 2008 (unwashed) and 2013 (washed and unwashed) were subjected to total copper analysis similar to the soil samples. The samples were subjected to acid digestion using EPA 3050B followed by ICP-AES analysis (EPA 6010B) with a reporting limit of 1 mg/kg.

4.3.4 Vegetation Data Analysis

To compare mean plant tissue concentrations of copper between time periods and between amendment and reference plots, one-tailed two-sample *t*-tests were performed and test assumptions met. Tissue concentrations before and after the white rain were first compared to evaluate the white rain effect. Tissue concentrations in the amendment plot before the white rain and after the white rain plus treatments were compared relative to the white rain effect to evaluate if treatment effects alone decreased copper uptake. As aforementioned, to account for differences between unwashed (2008) and washed (2013) plant tissue, a regression was developed between washed and unwashed tissue concentrations in 2013 (**Appendix B-2**) to develop a correction factor (0.9282) that was applied to unwashed tissue.

To account for differences between plant tissue collected in the spring 2008 (March), when tissue is dormant, versus tissue collected in the fall, when plants are in their growing cycle, a dormancy bias of 35 percent was estimated by comparing a bioaccumulation model developed on an independent dataset to a bioaccumulation model developed using the amendment plot soil and plant tissue data. The independent dataset were the 21 upland ERA 1999 tissue copper concentrations, which were plotted against pCu measured in 1999 to develop a bioaccumulation model. The regression equation of this site-specific model should be applicable to the amendment plots. Therefore, the dormancy bias was estimated by developing a similar bioaccumulation model with the amendment plot data[11], except the 2008 pre-treatment data first were adjusted downward to compensate for the dormancy bias until the bioaccumulation models were similar. A 35 percent decrease in 2008 data plotted with other 2013 amendment plot data produced a regression equation similar to the ERA equation (Cu_{tissue} = 143.2-15.0*pCu for ERA plots versus Cu_{tissue} = 143.2-18.7*pCu for amendment plots). Therefore, the 2008 tissue data were adjusted downward in concentration by 35 percent before conducting any statistical analyses.

Trend analyses were performed on the circular plot vegetation community data to evaluate changes in total percent cover, Shannon-Wiener species diversity, richness, and evenness from each amendment protocol. Additionally, changes in percent of vegetation that was native, annual, grass, or non-woody were evaluated. These variables were plotted on graphs to qualitatively compare their values: (1) before and after treatment, (2) between amendment plots and untreated reference plots, and (3) over time after treatment. A statistical BACI analysis could not be completed on the vegetation community parameters because only one sample was collected from the 0.01-acre circular plots on reference plots. Instead, as was conducted for soil, the trend in the "difference between amendment and reference plots" for each community parameter was statistically evaluated post-amendment over time (with linear or non-linear regressions) and qualitatively compared before and after amendment/tilling and at the end of 5 years to identify any improvements[12].

The vegetation characteristics were compared before and after the white rain in reference plots to evaluate the effect of the white rain, and then compared before the white rain to the community after it was affected by both the white rain and amendments. The effect of the white rain was considered to evaluate the success of the treatments in reaching the desired target of increasing diversity, cover, richness, and grass and non-

---

[11] Bioaccumulation models were developed on unwashed data available for ERA plots; therefore, the bioaccumulation model for amendment plots was also based on unwashed tissue concentrations. Tissue concentrations for ERA plots were estimated using the approach described in Section 7.7.

[12] However, the mean value of a community parameter post-treatment was also compared statistically to the single pre-treatment, pre-white rain estimate in a one-sample t-test to assist in final qualitative interpretations as to whether the parameter might have changed relative to the post-treatment variability in the parameter.

woody cover without excessive annual species invasion In addition, a community analysis (Canonical Correspondence Analysis [CCA]; ter Braak and Cajo 1986 and ter Braak and Verdonschot 1995) was performed in the statistical program R (vegan package, Oksanen et al. 2013) on vegetation data to determine the soil and environmental parameters most correlated with differences in vegetative community composition between the amended and adjacent reference plots. Such an analysis assisted in identifying what aspects of the treatments (disturbance, organic carbon, lime changing pH, tilling) were most strongly affecting the plant community.

4.4 Annual Reporting

Monitoring reports were completed annually (Arcadis 2010b, 2011b, 2012, 2013) to satisfy the annual monitoring requirement stipulated in the Work Plan. This Report is the final report and includes documentation of soil and vegetation sampling results after 5 years, the final statistical evaluations of the amendment effectiveness, and examines whether success criteria defined in the work plan were met (Arcadis 2008). This report also assesses the usefulness of the three remedial technologies to be formally evaluated as part of the STSIU FS.

5. Results

Results are discussed in the following subsections based on the specific hypotheses being tested as part of the study. Summary tables and figures are included at the end of the document text, and additional data or analyses are presented in **Appendix C** (soil) and **Appendix B** (vegetation). Photographs from the fall and spring sampling of the amendment and adjacent reference plots pre-amendment over the 5-year post-monitoring period are provided in **Appendix D**. Rangeland condition data are provided in **Appendix A**. Data directly from the laboratories are provided in **Appendix E**[13]. Soil concentrations discussed in this report are for surface soils 0 to 6 inches deep, unless otherwise noted. Subsurface soil data are reported in **Appendix C** and discussed in Section 5.2.7.

Mean concentrations (see **Table 4**), temporal trends (see **Figures 4a** and **Figure 4b**), and mean differences between amendment and reference plots (**Table 6** and **Figure 5**) for key soil parameters associated with these plots are discussed below. The parameters include pH, total copper, TOC, soluble copper, pCu, and C:N ratio. Mean values for copper concentration in plant tissue are provided in **Tables 7** and **Table 8** and are illustrated on **Figure 6.** Soil ABA results are presented on **Figures 7a** and **7b.**

Vegetation parameters important to wildlife and livestock are also discussed below including trends over time in proportion of community in early successional annual life forms (annual grasses and forbs), illustrated on **Figure 8**. The temporal trends in mean percent cover and diversity measures (richness, Shannon diversity, and Shannon evenness) are presented on **Figures 9a** and **9b. Figure 10** shows the proportion of vegetation in non-woody and grass vegetation over time. Mean differences between cover and diversity measures among amendment and reference plots are shown on **Figure 11**. **Figure 12** shows the change in the percent in native species over time. **Figures 13a, 13b,** and **13c** show the relationship between soil chemistry and species composition in the plot communities. Details on changes in species composition are discussed in **Appendix B-3**.

---

[13] Except the oldest soil laboratory data for July 2008 and May 2008

5.1 White Rain Effect

Hypothesis: Soil pH and pCu will increase, soluble copper will decrease, and plant tissue copper concentrations will decrease on amendment and reference plots as a result of the white rain that occurred in January 2008. The effect will persist.

Soil pH. Surface soil samples were collected in spring 2006 and spring 2008 to represent baseline pH before treatment. The white rain fell between these two periods. As hypothesized, the white rain significantly increased pH on amendment and adjacent reference plots between spring 2006 and spring 2008 (ANOVA, P<0.0001, n = 41, **Appendix C-1**). The mean pH increased significantly (P<0.0001, ANOVA) by 1.5 standard units (s.u.) in the plots planned to be amended (excludes West plot, which had high initial pH, see data in **Table 1**)[14]. The pH increase in the steeper Northeast plot was less than the other two plots (0.5 increase vs. 1.2 for East and 2.9 for North, significant interaction term between location and year of P = 0.016) but still significant (*t*-test, P <0.0001).

As a supporting line of evidence of the white rain effect, a comparison of 1999 and 2010 data on ERA plots that exhibited low pH (<5.5 s.u.) reported in Arcadis 2017a showed a similar magnitude of increase after the white rain, an increase of 1.2 s.u. (from 4.7 to 6.0; *t*-test, P < 0.0001).

Notably, pH in the West amendment plot increased after the white rain (to pH 8.2 in May/June 2008, **Appendix C-1**), despite having a high initial pH of 6.5 in 2006. As is often seen in high pH soils that initially increased from the white rain event (see **Figure 7** in Arcadis 2017a), this high West plot pH has been significantly but slowly decreasing over time (see **Table 4**) in both the West amendment and reference plots (see **Figure 4a**, P = 0.002). By 2013, the two West plots averaged a pH of 7.6 (but was higher at a pH of 8.0 by 2014 in the West reference plot monitored as part of the pH monitoring program; Arcadis 2017a). The pH increase of the poorly buffered soils (more acidic pH)

---

[14] The pH and pCu estimates may be reported slightly differently for 2008 in different tables depending on whether field and lab pH data are combined and if plots were moved; see **Tables 1** and **4** and **Appendix C-1**; statistical analyses were performed on the all data. Additionally, an error was found in previous annual reports. East and Northeast plots (formerly East A and East B in 2006, renamed East B and East A in 2008, respectively) soil data were switched in 2008 and 2009, which was corrected in this report.

following the white rain event is consistent with neutralization of active acidity, whereas the slow decrease in pH dropping from 8.3 in the higher pH West plot amendment and reference plots suggests that the excess alkalinity associated with the white rain might be slowly depleting from the surface soil. This is uncertain given the variability in pH and more recent increase to 8.0. Overall, the pH monitoring program from 2010 to 2014, which evaluated the permanence of the increase in pH in poorly buffered soils, found that the initial increase from the white rain had been sustained through 2014 (Arcadis 2017a).

These pH changes, resulting from the white rain event, partially disrupted the Amendment Study by effectively liming both the amendment and reference plots. After the white rain, each of the amendment plots met the target goal of pH 5.5 or greater (see **Table 1**, revised study design). The need for adding lime as part of this pilot study was re-evaluated given that the target was already met. It was decided to add more lime because of the possibility that plots would have fluctuated in and out of the target range over time, as has been seen with the reference plots (see **Table 4**). It was necessary to consider the increase in pH from the white rain when deciding how much lime to apply, and the amount planned was reduced from 6.6 to 1.3 t/ac, making the treatment effect smaller and likely more difficult to detect. However, the effect of the white rain can be evaluated as another line of evidence for effectiveness of liming that does not also include adding organic matter because the white rain essentially deposited lime, neutralizing the active acidity that was present from the smelter (see **Appendix B-21** where these other lines of evidence are considered).

<u>Soil pCu</u>. Total copper concentrations required to calculate pCu were not collected from the amendment or reference plots before the white rain event; therefore, the effect of the white rain on pCu is difficult to calculate for these plots. However, if total copper concentrations just after the white rain in May 2008 are assumed to be comparable to those before the white rain (collected in 2006), they can be used to calculate pCu in 2006. When this method is used with laboratory pH data, the increase in pCu from the white rain is estimated to be from 2.04 to 4.31 in the North amendment plot, from 3.5 to 4.61 in the East amendment plot, and from 3.26 to 3.50 in the Northeast amendment plot. These pCu increases are significant at $P < 0.10$ (two-sample *t*-test, $P = 0.06$), which is the target level for assigning significance due to the low sample size and high variability of these data ($n = 5,6$). The average increase in pCu across all three plots using this method is 1.2 s.u., which would mean that the white rain increased the average pCu of the three plots from about 2.9 to 4.1 s.u.

The data presented in the white rain report (Arcadis 2017a) showed that pCu significantly increased from 4.6 to 6.0 due to the white rain ($P < 0.0001$) in the STSIU by 2010 in locations that exhibited low pH in 1999 (less than the 5.5 threshold). If it can be assumed that the same happened on the three amendment plots, then pCu increased by about 1.4 s.u. on the amendment plots. Surprisingly, this 1.4 s.u. increase was predicted using the method above of substituting 2008 copper data for 2006 copper data to calculate pCu. This consistent result supports the hypothesis of the white rain increasing pCu by at least 1 s.u. in low pH locations.

Soluble Copper. Similar to pCu, soluble copper was not estimated on the amendment or reference plots before the white rain event. The only pre-event data available are the 1999 ERA plot data. Average soluble copper in 1999 on non-collocated ERA sites with pH below the pH 5.5 threshold (ERA 1, 2, 3, 4, 7, 9, 13) was 0.56 mg/L ($n = 8$). This soluble copper concentration did not significantly change after the white rain, though it tended to be lower at 0.17 mg/L on amendment plots in May 2008 after the white rain but before amendment ($n = 6$, one-way ANOVA on log-transformed soluble copper, $P = 0.219$). No West plot data were included in this analysis because they were unavailable in May 2008. The hypothesis that soluble copper would significantly decrease from the white rain was not supported by ERA data, but there is uncertainty as to the applicability of ERA results to the amendment study area (see Section 7.2).

Persistence of pH and pCu. After the white rain, the pH and pCu increase observed in the East and North reference plots was persistent for 5 years. Based on data in the reference plots from 2010 to 2013, pCu (but not necessarily pH) increased to even higher levels over time (**Figures 4a** and **4b**). It is uncertain if the increase is from natural attenuation or is an artifact of variability in the data from sampling period to sampling period. Persistence of the pH increase from the white rain is supported for the reference plots when evaluated over the 5-year period specified in the approved work plan, and it is also supported in the draft white rain report up to 2014 (Arcadis 2017a). For example, over the monitoring period, the pH in the North reference plot increased greatly from about 3 s.u. before the white rain to 5.29 s.u. just after the white rain (based on the adjacent amendment plot pH measurement of 3.7 in 2006, pH in the reference plot was likely somewhere between 3 and 4 in 2006, likely at 3 s.u.[15]). In October 2013, after 5

---

[15] Note that the reference plot pH was not measured in 2006, but it is assumed to be lower than that of the amendment plot based on the difference (0.84 s.u.) in pH observed between

years, pH averaged even higher at 5.79. For the prior sampling period in April 2013, the pH was at its highest level at 6.23. Therefore, the results do not show trends toward a return of pH to the pre-white rain value of around 3. Also, the statistical analysis for both the North and East reference plots support that the regression fit through the pH of sampling periods post-white rain is not significantly decreasing (no minus sign next to North or East reference plot legend on **Figure 5**) and therefore is not decreasing over time (but the East reference plot is significantly increasing as indicated by its plus sign). A slight decline over the last year in the North plot does not support a concern for lack of persistence, given that the fluctuations are small relative to the large increase from the white rain (true for both North and East reference plots). Persistence beyond 5 years will be evaluated with additional monitoring during the FS.

The ABA data in this report (**Figures 7a** and **7b**, see **Appendix C-7**) and in the white rain report (Arcadis 2017a) also support persistence of the pH increase from the white rain in the North and East reference plots, which is expected to continue over the long term because they meet the MMD criteria of greater than -5 t $CaCO_3$/kt, which means they have low likelihood of acid generation, and because additional sources of acidity are unlikely after the cessation of the smelter operation and capping of the tailings. Also, pH has been sustained at above 5.5 since 2012 in both plots (**Figure 4a**), indicating that all active acidity likely has been neutralized in the plots based on Thomas (1996).

The steeper Northeast reference plot exhibits highly variable pH and pCu, and they also show no upward or downward overall trend (**Figures 4a** and **4b**). The lack of a significant slope or trend over time indicates that there is no decrease in pH or pCu, which supports persistence of the white rain effect to date. However, the Northeast reference plot pH increased less from the white rain than the North and East reference plots (by only 0.5 s.u.). The fluctuations in the Northeast reference plot are large relative to the small increase from the white rain, whereas the other two plots experienced a very large increase in pH from the white rain with later fluctuations much smaller than the initial increase. It is more difficult to assess persistence in the Northeast plot because a fluctuation can dip into the range of the pre-white rain pH, whereas it would need to decrease a large amount for the other plots to return to the pre-white rain pH. The ABA data show that this plot met the MMD criteria of greater than -5 t $CaCO_3$/kt, but the pH is

---

the reference plot and amendment plot when measured extensively in 2008 (**Appendix C-1**). Given that the amendment plot pH was 3.7, the reference plot pH could have been about 3.

below 5.5, which supports uncertainty with regard to the future persistence of the white rain effect on the Northeast plot.

For the pCu target of success, only the North reference plot achieved the pre-FS RAC level of 5 or greater by 2013. As mentioned above, pH did not significantly change. The increase appears to be due to a reduction in copper over time (significant trend in North reference plot in **Figure 4b**) The pCu at the poor rangeland East reference plot was 4.86 in October 2013, and at 3.62 at the Northeast reference plot by that date (**Figure 4b**). The significant upward trend of the pCu of the East reference plot (**Figure 4b**) suggests that it may eventually reach that pre-FS RAC level. However, the trend is highly uncertain because the white rain report (2017) indicates that the pCu of the East reference plot dropped from 5.07 in 2013 to 3.93 in 2014[16]. However, the sampling of this plot for the white rain report covers a larger area (0.25 ha) than sampling for the amendment study (0.09 ha) and may not be fully comparable. Also, soil pCu is variable (because pH and copper are variable), reducing the ability to be certain if trends within 5 years are random fluctuations are actual trends.

Plant Tissue Copper Concentrations. To evaluate white rain effects on plant uptake of copper, mean copper concentrations of plant tissue collected from March 2008 amendment plots (representing pre-amendment and pre-white rain conditions) were compared to tissue sampled in October 2013 on adjacent untreated reference plots representing post-white rain samples (**Tables 7** and **8**). Though the March 2008 tissue samples were collected post-white rain, they represent pre-white rain concentrations because the leaves and seeds collected grew during the previous growing season before the white rain (plants were still dormant in March 2008). The comparison to 2013 results assumes that the white rain effect persisted through 2013.

Dormant season tissue can exhibit higher metal concentrations than growing season tissue (Hunter et al. 1987, Johnson et al. 2006). Metals in the plant cells may be allocated to cell wall material during dormancy (Koelling 1996), and the cytoplasm and soluble content of the cell is reduced (especially if ruptured during freezing), which increases metal concentrations in herbaceous plant tissue during dormancy (Lyons et al. 2012). Therefore, the 2008 concentrations were reduced by 35 percent to account for this dormancy bias before statistically comparing means, as discussed in Section 7.3.4.

---

[16] Copper increased from 923 to 1,020 mg/kg and pH decreased from 6.0 to 4.9 between 2013 and 2014 on the East reference plot.

Additionally, concentrations were adjusted to “washed” concentrations using the regression discussed in that Section.

The plant concentrations in the West plots are expected to respond differently because of their high soil pH before the white rain, and the Northeast plot may respond differently than the tilled plots because it was not tilled. Therefore, tissue concentrations were compared in several ways: with all plots but the West plots, with only the tilled plots, and with the West plots only.

Ideally, concentrations of copper in the same species should be statistically compared before and after treatments because copper uptake, translocation to leaves, and copper tolerance mechanisms vary by species (Ross 1994). However, individual species could not be compared because of data limitations. Species available in quantities sufficient to sample on the untreated amendment plots changed between 2008 and 2013 (see **Appendix B-1** for foliage sampling methods). Though data are reported and compared qualitatively by individual species (see **Table 8**), statistical analyses were performed on averages calculated for all species combined (see **Table 7**) to have sufficient sample sizes for such analyses.

Because deep-rooted woody plants may respond differently than herbaceous plants, analyses were also conducted on just herbaceous species. Honey mesquite (known to have very deep roots, Phillips 1963) was the only shrub sampled and was removed from the mean tissue concentrations for this second analysis (**Table 7).** Of the species sampled, mesquite exhibited the highest copper concentrations in 2013 (**Table 8**), and its removal lowered the concentration average. Mesquite is not highly sensitive to copper toxicity and survives even in sites with very low pCu (such as ERA 1, Newfields 2005). The reduction in herbaceous species may be of most interest.

Post-white rain, plants on amendment study reference plots (excluding the West plot) in fall 2013 exhibited substantially lower plant tissue copper concentrations (washed) than pre-white rain estimates whether or not mesquite was included or West or Northeast plots were included ($P<0.03$, **Table 7**). White rain reduced concentrations by 53 to 72 percent, depending on the plots and species included. The average concentration of all species sampled in the untreated plots (excluding the West plots) decreased from an average of 83 mg/kg before the white rain in March 2008 to an average of 32 mg/kg in October 2013 after the white rain (**Table 7**), only 12 mg/kg higher than the upper limit of the nutritional requirement range for agricultural crops of 8 to 20 mg/kg for copper (Schulte and Kelling 1991). Similarly, the plant tissue from the two excluded West control plots decreased considerably from 69 mg/kg in pre-white rain conditions to 25 mg/kg copper in 2013 after the white rain. When only herbaceous plants were included, the post-white rain concentrations were even lower (excluding the West plots) at 23 mg/kg when including the Northeast plot and at 20 mg/kg excluding that location (i.e., only including the two tilled plot locations: North and East).[17]

Table 8 shows the tissue concentrations by individual species when they were collected unwashed in 2008, when they were adjusted to washed samples in 2008, and when they were collected twice (as washed and unwashed) in 2013 (n = 1 composite collected across the plot per species per sampling event). Separated by species, the results are similar to the comparison of averages in that species with high copper concentrations exhibited decreased copper levels after the white rain. Specifically, copper concentrations in sideoats grama (*Bouteloua curtipendula*) tissue (washed) decreased on untreated plots in the amendment study after the white rain affected the plants. The decrease before adjusting for the dormancy bias was by 87 percent at the Northeast plot, 37 percent at the West plot, and there was no decrease at the North plot (compare pre-amendment washed data to October 2013 reference washed data in **Table 8**).

Results are not presented for the East plot because sideoats grama was not present on the East plot before the white rain, and no other species comparisons to evaluate the white rain effect were possible on that plot. The North plot exhibited no decrease in sideoats grama because the concentration was already low in this species before the white rain (only 10.2 mg/kg). In contrast, species with high copper concentrations before the white rain (vine mesquite [*Panicum obtusum*]), exhibited copper levels that decreased by 81 percent at the North plot.

Applying the dormancy bias adjustment shrinks the magnitude of the reduction down to 79 and 3 percent for sideoats grama in the Northeast and West plots, respectively. When adjusted, the vine mesquite concentration in the North plot decreased by 71 percent. Therefore, for plants and locations with high copper bioaccumulation, the white rain effectively reduced uptake and appeared to meet the assumption of producing a persistent effect through 2013.

Figure 6 illustrates the average reduction in tissue copper concentrations (washed) across sampled species resulting from the white rain for the tilled plots (North and East),

---

[17] **Appendices B-16** and **B-17** summarize the original data unwashed and washed, respectively, before and after dormancy bias adjustments in the 2008 data.

limed plot (Northeast plot), and West control plots, first unadjusted for the dormancy bias and then adjusted. To evaluate if the dormancy bias adjustment is reasonable, **Figure 6** also compares the amendment pre-white concentrations to an independent pre-white rain dataset: the 1999 tissue concentrations at depressed pH ERA plots on the STSIU (ERA 1, 2, 3, 4, 7, 9, 10, and 13 at pH < 5.5). This ERA dataset exhibits an average soil pH similar to the three amendment plots (4.8 compared to amendment plot average of 4.6 when excluding West plots) but higher estimated average soil pCu (4.4 vs. 2.9; **Appendix B-15**). Using these pCu estimates, the ERA pCu bioaccumulation model predicts uptake during the pre-white rain period of 100 mg/kg and 77 mg/kg of copper into plant tissue on average for the amendment plots and ERA dataset, respectively, a 23 percent difference. The observed difference is somewhat higher at 35 percent (**Figure 6**). The dormancy adjustment in 2008 of 35 percent is within the “ballpark” of a reasonable estimate, though it could be underestimating the magnitude of the white rain effect.

5.2 Effectiveness of Amendment/Tilling at Improving Soil Quality

The following subsections discuss the effectiveness of the lime and organic amendments and tilling at improving quality of the soil chemistry. Five hypotheses were identified for soil chemistry. Each subsection below summarizes a hypothesis and provides the statistical analysis and data interpretation used to evaluate it. **Table 2** summarizes all hypotheses tested statistically (except that No. 7 had a qualitative comparison of cover and diversity measures) and the results.

5.2.1 Hypothesis No. 1: Amendment using lime with or without tilling will increase pH, and the increase will persist and exceed the target pH of 5.5.

The before-amendment period (May 2008) and after-amendment period (average of all sampling events after, up to, and through 2013) were statistically compared using BACI. First, the effect of lime amendments was evaluated and then the effect of tilling combined with lime amendments was evaluated (organic matter was also included with lime, but pH changes are assumed to be from the lime). Only the surface layer chemistry was analyzed because the subsurface was not affected to much extent, as discussed in **Section 5.2.7**.

Although the lime amendment increased the mean soil pH by 0.12 s.u. beyond the white rain effect (**Table 9a**), the BACI interaction term was not significant at P = 0.19 (**Table 9b**). The change in pH in unlimed reference plots was in the opposite direction (0.10

s.u. decrease; **Figure 14**) but these magnitudes of change are too small to be significant. Liming the plots after the white rain did not significantly change the pH.

The effect of tilling on pH was evaluated in a BACI by comparing all tilled plots to untilled plots (i.e., northeast and reference plots). The interaction term was almost significant for pH (P = 0.07), but not pCu (P = 0.20; **Tables 9a** and **9b**). The pH result indicates that, with 90 percent confidence (see **Section 7.2**), tilling plus lime amendments may have increased soil pH on average from 6.8 to 7.1 mg/kg (0.3 mg/kg increase), which contrasts with the slight drop in pH from 6.2 to 6.1 observed between pre- and post-treatment periods in the untilled plots (**Figure 15**).

The slight increase in pH from the white rain and the tilling plus amendments persisted over the 5-year Amendment Study period when considering only the amendment plot trends (see **Figure 4a**). However, when the analysis is related back to the reference plot trends, the East amendment plot regression results suggest that there may be a lack of benefit from the tilling in the East amendment plot, but not in the North amendment plot, when evaluating soil chemistry (when evaluating effect on vegetation, the North amendment plot does not show benefits either; see Section 5.3.3) . The lack of benefit for the East amendment plot is uncertain because in 2014, the upward pCu trend was no longer obvious, as discussed above.

Figure 5 displays the differences in mean parameters between the amendment and reference plots. The decline in the difference in mean pH between the amendment and reference plots (East and North) is primarily due to an increase in pH over time on the reference plots rather than a decline in pH on the treatment plots (significant increase in both reference plots shown since 2010 on **Figure 4a**). The decline in the difference is only significant on **Figure 5** for the East plots, indicating that the benefit of amendments and tilling is diminishing over time in this plot because the reference plot is increasing in pH without such treatments. Specifically, after 5 years, the East amendment plot exhibited a mean pH of 7.04, while the mean pH of the East reference plot increased to 5.95 in 2013 (see **Table 4**). This difference of 1.09 was about the magnitude of the difference between the two plots before applying the treatments. In other words, by 2013, the pH difference decreased to the same difference level observed before treatments for the East plots (see **Figure 4a**), which suggests no benefit from treatment by 2013.

For the North plots, the decline in the pH difference is not statistically significant, and it is unlikely that the benefit is diminishing (very low confidence of 56 percent that it is diminishing; **Figure 5**). By 2013, the pH difference in this plot was still greater than the difference before treatment by about 0.25 s.u. Although the North amendment plot shows a two sampling period (more than 1 year) decline in pH in 2013, the pH still falls within the range of fluctuations observed in previous years (**Figure 4a**). Also, the pH is very high: above 6.0 (**Figure 4a**). Therefore, tilling lime into the soil may have benefited the soil chemistry in the North amendment plot (but not necessarily the vegetation community; see Section 5.3.3).

The loss of benefit is different than lack of persistence in the pH data. The loss of benefit means that the improvements can occur without the treatments; therefore, applying treatments does not result in a benefit of higher pH beyond that which would occur without applying any treatments (because natural attenuation was able to increase pH instead). The loss of persistence means that the pH is declining over time, which has not been observed on **Figure 4a** for the tilled plots. As discussed in the white rain report, the tilling plus lime effect in these two plots is expected to persist because all active acidity has been neutralized in plots that exhibit a pH above 5.5 (Thomas 1996), the NNP meet MMD criteria, as discussed in the ABA results below, and additional sources of acidity are unlikely with cessation of the smelter operation and capping of the tailings. These two plots exhibit pH well above 5.5, even with the fluctuations.

The ABA results for the amendment plots (sampled only once post-treatment in December 2008 on amendment plots; **Figures 7a** and **7b***,* see **Appendix C-7**) support persistence of the increased pH in the plots where there was an almost significant increase (North and East amendment plots). The North and East amendment plots exhibited a positive NNP; therefore, the surface soils of these plots met the MMD soil and overburden suitability guidelines of an NNP greater than -5 t $CaCO_3$/kt (MMD 1996).

Notably, all of the other plots in the Amendment study also met this criterion. As mentioned above, the most alkaline pH was observed for the West control reference plot (mean pH 8.16), which also exhibited the highest mean NNP (141 t $CaCO_3$/kt) and NPR (308) compared to the other reference and amendment plots (even after the other plots were amended with lime). The West control plots easily meet the NNP criteria because of the abundance of calcium carbonates in the geological formation creating the soils, but the other plots may nonetheless have enough calcium carbonates from the white rain to avoid becoming strongly acid generating. The white rain may be influencing the ABA results for the other reference soils by neutralizing considerable amounts of active acidity. In addition to the NNP criteria, both the reference and amendment plots were designated as non-PAG based on meeting or exceeding an NPR of 2, with the exception of the East reference plot, which was designated as uncertain based on a mean NPR of 1.3. In contrast, a higher mean NPR of 84.8 was associated with the adjacent East amendment plot surface soil, consistent with residual alkalinity from the lime amendment.

The Northeast amendment plot did not appear to benefit from treatments but averaged pH at 5.49 after application of the amendments nonetheless because of the white rain effect. Although its pH was less consistently above 5.5 than at the other plots, it exhibited an NNP above the MMD criteria since December 2008, suggesting its pH may not revert back to lower values. The white rain report (Arcadis 2017a) shows that soils with pH above 5.1 almost always (with one exception) exhibit NNP above the MMD criteria and likely will persist at pH levels observed. The Northeast amendment plot has exhibited pH above 5.1 since fall 2009. The unusual low pH in December 2009 is based on two samples and may be from very localized areas in the plot and not representative of the plot average (when eight samples were taken later in 2012 and 2013, it is much higher on average; **Table 4**). The Northeast amendment plot trend appears to be more representative of trends observed after the white rain in the Northeast reference plot (if the comparison of the two Northeast plots on **Figure 4a** is adjusted for the average pH of the reference plot being lower; **Appendix C-1**), rather than responding to the amendments. The pattern is consistent with finding no effect of treatments on this plot (which was limed) but not tilled and was situated on a slope.

The pyritic/sulfide sulfur content analysis can also provide some insights into the persistence of the pH changes, with low values indicating higher likelihood of persistence. Sulfur content was low based on the mean pyritic/sulfide sulfur of 0.02 percent for the amendment plot surface soils and 0.05 percent for the reference plot surface soils (see **Appendix C-7**). The pyritic/sulfide sulfur content of the reference plot surface soils was skewed slightly higher by the East reference plot, which averaged 0.10 percent. The East reference plot has layers of windblown tailings, as represented by the comparatively elevated pyritic/sulfide sulfur content, whereas the other reference plots were not affected by tailings. The pH trend upward in the East reference plot may be due to the white rain neutralizing the active acidity from sulfuric acid in this plot. However, the pyritic/sulfide sulfur is not consistently decreasing, making the interpretation of the trend uncertain.

In summary, the treatments were only beneficial for increasing pH on relatively flat plots where the lime and organic matter were tilled into the soil at an 8-inch depth. Tilling may distribute lime into these top inches and neutralize acidity in that depth layer more quickly than not tilling. Without tilling, only the top couple of inches may be neutralized after spraying the soil with lime (Peters and Kelling 1998); it may take several years for the lime to migrate deeper into the soil without tilling (Mamo et al. 2009) unless organic acids are abundant enough to move the calcium carbonate downward more rapidly (high organic matter has moved lime down to almost 8 inches; Bot and Benitas 2005).

Organic matter was added and may have facilitated downward migration of lime. However, the results show that the pH in the tilled plots increased more than in the non-tilled plots that received lime and organic matter. The white rain may have already neutralized the first 2 to 3 inches at the surface. Further improvement in pH in the top 6 inches (surface depth analyzed for pH) may require tilling in the lime to at least this depth or letting nature move it downward over a longer period of time than this 5-year study.

An uncertainty is that the increase in pH in the tilled plots may be unrelated to tilling. The Northeast plot was not tilled, but it may not have demonstrated a response to pH possibly because it was the only treated plot on a steep slope. The sprayed lime and organic matter may have washed downslope before infiltrating, reducing its response to the amendments. This location’s reference plot also exhibited the smallest improvement from white rain (0.5 increase in pH), possibly because of its steepness. The increase in pH observed in the more level plots may have occurred on the untilled Northeast plot as well if it had been on relatively level ground.

Tilling is the more likely explanation because all plots exhibited pH of 5.5 or greater on average in the 6-inch depth sample before treatment. Improvements in pH are unlikely when the pH is that high because buffering capacity is typically high (Arcadis 2017a). However, if the lower 4 inches of the surface 6 inches were still relatively acidic, and only the surface 2 inches were very high in pH after the white rain (but average pH over 6 inches was still > 5.5), the tilling may have mixed the lime into deeper layers and facilitated neutralization of the lower inches more quickly. The increase in pH after tilling relative to reference was small (net difference of 0.3 s.u.; **Figure 15**), making it difficult to detect pH changes with certainty given that the power of the tests are most confident for detecting a 0.5 pH increase or more (see **Section 7.2**).

Tilling may accelerate neutralization, but may not be necessary if the white rain is ultimately able to neutralize soils to the target pH of 5 without tilling. The East reference plot had no amendments added, yet it also increased in pH by a small amount similar to that of the East amendment plot by the end of 5 years (from about 4.5 to 6 in reference plot compared to from about 5.5 to 7 in the amendment plot). The white rain’s lime may have been infiltrating downward into the soil profile slowly over time in that plot. The surface inch was tailing material already high in pH in 2006 in this area even before the white rain (~6.5; **Appendix C-3**). Below the surface inch, the soil was very acidic (~4 s.u.). As such, the improvement from neutralizing the acidity would take more time for the East reference plot because it must migrate deeper to reach the acidic layer[18]. This delayed effect is less apparent in the North reference plot, probably because this plot did not have tailing material on the surface and averaged pH above 5.5 consistently after the white rain, whereas the East reference plot was below pH of 5 until 2012. Most of the STSIU does not have an inch of tailing on top of the soil and may have responded more quickly to the white rain, as observed in the white rain report (Arcadis 2017a). However, for the Northeast reference plot, which did not have tailing on the surface, pH fluctuated around 5 and did not improve over time, indicating that it probably did not have improvement with lime infiltration to deeper layers after the white rain. Possibly, the lack of improvement was because of runoff of lime from the steeper plot and its soil had more buffering capacity (because of more topsoil) than the eroded East reference plot.

In summary, all treated plots successfully met the target criteria of pH 5.5 or greater in fall 2013 (see **Table 4**) due to the white rain, the treatments, or both. The hypothesis that an initial increase in pH would be observed as a result of simply applying a lime amendment (plus organic matter) after the white rain was not supported by the study findings; however, the addition of tilling likely does cause an increase in pH that persists over time. It is unknown if the treatments are beneficial in the long term given that the white rain contribution of alkalinity may still be migrating deeper into the soil. Considerable uncertainty is associated with these conclusions, which is discussed in Section 7.2.2.

5.2.2 Hypothesis No. 2: Tilling (to 8-inch depth) will decrease total copper in surface soil, and the decrease will persist, whereas lime and organic matter (removing effect of tilling) will not affect total copper because copper will remain in the surface soils.

The hypothesis that tilling to 8 inches would significantly decrease average total copper in the top 6 inches was not supported by the study findings. The BACI results carry some uncertainty because copper concentrations pre-amendment are estimated from less collocated reference areas (see **Appendix C-2**), not from the exact adjacent reference plot in the study. Tilling decreased total copper concentrations by a mean of 557 mg/kg (least square mean difference in the two tilled plots compared to untilled plots, **Table 9a** and **Figure 15**). The interaction term was not significant (P = 0.91) in the BACI, however,

---

[18] This pH increase in East reference plot over time is uncertain because low pH was identified again in this area in 2014, but the 2014 plot monitored for the pH monitoring program (see Arcadis 2017a) is much larger and may not be representative.

because the mean copper concentration of untilled plots (all untilled plots were used as reference) also decreased by a similar amount (by 604 mg/kg; see **Tables 9a and 9b, Figure 15,** and **Figure 4a**). Even if sample size were larger with greater power to detect differences (power is low, see Section 7.2), the mean differences are too similar between reference and amendment plots to support that treatments could have affected copper concentration (also see analysis without less collocated plots in Section 7.3.3). If the plots had been tilled to deeper than 8 inches, the reduction may have been larger and significant.

The hypothesis that lime and organic matter would not change total copper was supported, as shown by a non-significant interaction term in the BACI (P = 0.67, 500 mg/kg decrease in amendment plots, 659 mg/kg decrease in reference plots, see **Table 9b** and **Figure 4a**), indicating that copper concentrations did not decrease more than in the adjacent unamended reference or control plots (**Figure 14**). Notably, copper concentrations significantly decreased over time in both the North amendment and North reference plots, whereas one of the West amendment plots exhibited a significant increase in copper concentrations (see **Figure 4a**). It is uncertain if these are real trends or random variability, given the high variability observed in copper concentrations (see Section 7.2).

5.2.3 Hypothesis No. 3: Amendment of lime/organic matter and/or tilling will increase pCu, and this increase will persist.

The hypothesis that an initial increase in pCu would occur from addition of lime/organic matter was not supported. Although tilling plus addition of lime and organic matter (regardless of the organic matter rate applied) increased mean pCu by an additional 1.2 s.u. beyond the white rain effect, the untilled plots also exhibited an increase between the pre- and post-treatment periods of 0.41. (**Table 9a, Figure 7b**). As a result, the increase of 1.2 was not significant (demonstrated by insignificant interaction term at P = 0.2; see **Table 9b.**) Also, lime/organic matter did not significantly increase pCu (interaction term of P = 0.41, see **Table 9b**).

With larger sample sizes, the increases might be significant but are difficult to detect because of the low power of the statistical test for the tilling analysis (see Section 7.2) and because the expected increase in pCu from just increasing pH by liming is small for the lime amendment analysis. Liming rates applied in this study were deliberately kept low because white rain already limed the plots, and less was needed.

If samples sizes were larger, providing more statistical power, it is possible that the difference in the increase between tilled and untilled plots (1.2 – 0.41 = 0.79) could become significant. The increase in pCu, whether significant or not, persisted over the 5-year monitoring period when evaluating only the amendment plot data. When compared to reference plots, the increase relative to untreated plots in the East and North amendment plots may be diminishing over time because the East and North reference plots are increasing in pCu over time, whereas pCu has not increased in the amendment plots during this post-amendment period (see **Figure 4b**). The diminishing trend, based on the difference between reference and amendment plots since 2010, is close to being significant, but not quite statistically significant for the North plot (too highly variable; P = 0.1595), though it is significant for the East plot (see **Figure 5,** which illustrates the difference in pCu between the treatment and reference plots).

The decline in the difference in mean pCu between the amendment and reference plots (**Figure 5**) is due in large part to the gradual increase in pCu in the reference plots over time (see **Figure 4b**). This trend applies mostly to the East plots, however, where the trend is statistically significant. The difference between the plots before treatment is about the same 5 years after the treatment in the East plot (but this conclusion depends on the less collocated data, see Section 7.2). The North and Northeast plots exhibit a slightly larger difference after 5 years, indicating that these plots possibly received some benefit, but the fact that the pCu is almost the same between the two plots in 2013 indicates that the size of the benefit may be negligible. The results could indicate that liming, tilling, and organic matter application is not very effective or needed because the white rain and any natural attenuation would have had the same effect on soil pCu five years after the white rain without treatment, as demonstrated by the untreated reference plots.

These analyses were conducted on calculated pCu. Measured pCu could not be used to evaluate effectiveness of treatments because it was only sampled in October 2013 on amendment and reference plots; no measured pCu data on the plots are available for the 10 other sampling periods or from before treatments or the white rain. Calculated pCu was deemed an adequate surrogate because it was verified to be significantly and highly correlated to measured pCu ($r^2 = 0.75$, $P < 0.0001$; see **Appendix C-8, C-9, C-10**), though it may be biased slightly low. In 2013, average calculated pCu consistently underestimated average measured pCu in the amendment locations around the historical smelter (by 0.93 s.u.), though sites around the smelter where pCu was measured for the phytotoxicity study exhibited less of an underestimate (using data from

Arcadis 2017b)[19]. The underestimation may be a result of calibration procedures used by the laboratory, which demonstrated non-linearity when pCu was greater than 9. The non-linearity outside of the pCu 4 through 9 range was ignored, and a regression fit was applied through the entire range of data from pCu of 4 to 15, which inflates the measured pCu slightly when pCu is greater than 5 (see **Appendix C-6**). Sample variability also likely played a role in the differences in calculated versus measured pCu around the smelter site.

The West control plots met the pre-FS RAC criteria before this pilot study began because, as mentioned previously, the area west of the smelter influenced by the Gila Conglomerate Formation and limestone outcrops naturally exhibits high pH and high pCu. As discussed in **Section 5.1**, of the reference plots, the untreated North reference plot recently reached the pCu pre-FS RAC of ≥ 5 (due to decrease in copper); pCu is also increasing in the East reference plot toward that threshold (due to increase in pH; October 2013 pCu was 4.86 compared to 3.22 in April 2010, see **Figure 4b**). These increases indicate that natural attenuation from and after the white rain could be occurring. Unfortunately, the high copper variability affects calculated pCu and makes this possibility highly uncertain, as seen by the decrease in pCu in the East reference plot to 3.93 in 2014 reported in the white rain report (Arcadis 2017a) after the monitoring for this amendment study was completed (but a larger area than the plot was sampled in 2014).

Of the three limed plots, only the two tilled plots met the pre-FS RAC for pCu of ≥ 5.0, which might support that the combination of liming, organic matter application, and tilling is effective for reaching the pre-FS RAC. However, the interaction term was not

---

[19] Comparison of calculated and measured pCu (measured pCu is in parenthesis) in surface soil in fall 2013 (also see table by depth stratum in **Appendix C-8**):

E Amend	E Ref	N Amend	N Ref	NE Amend	NE Ref	W Amend	W ref
6.14(7.13)	4.86(4.72)	5.43(5.99)	5.17(5.71)	3.72(4.50)	3.62 (3.62),	5.96 (8.95)	6.53 (8.26)

In 2006, before white rain/amendment, calculated pCu estimates were (in same plot order):

4.41 2.13 3.26 5.07

significant for pCu for any combination of liming, tilling, and organic matter additions tested (P > 0.2). This suggests that the treatment effect in the tilled plots was too small to detect with the power of the tests; the treatment did not improve the pCu enough beyond the changes and variability in pCu already occurring in the untreated plots.

The untilled Northeast plot also demonstrates little response in pCu to liming or organic matter additions (organic matter loading was highest in this plot), possibly because of the steep slope causing the lime and organic matter to run off rather than infiltrate into the soil. The number of different organic matter rates applied was too limited (n = 3) to develop a quantitative correlation among rates and pCu change, particularly because the plot with the highest rate was the steep-sloped plot that may have had organic matter run off the plot (organic matter was observed downslope). Nevertheless, high organic matter loadings were selected to offset the effect of organic matter runoff, and yet no increase in pCu was observed on this plot. This suggests that organic matter may not be helpful for improving pCu.

Overall, the results do not support that organic matter, lime, or tilling are significantly changing pCu for any treated plot beyond the effect of the white rain. Power for detecting a significant interaction term for pCu with a 1 pCu unit change was low at 45 percent, however (see Section 7.2), creating some uncertainty in this result.

5.2.4 Hypothesis No. 4: Amendment of lime, organic matter, and tilling will decrease soluble copper, and the decrease will persist.

This hypothesis of a beneficial effect of soluble copper is not supported for the two amendments applied together (lime and organic matter), nor with tilling added. Rather than decreasing, soluble copper concentrations initially increased in the three plots amended with lime and organic matter, whether tilled or not (see **Figure 4a**). When the data for the sampling event before lime/organic matter application (May 2008) were compared to the first sampling event after application (December 2008), soluble copper increased significantly by 0.81 mg/L (based on least square means; P = 0.02; **Table 10**). The increase was largest in the non-tilled Northeast plot, and smaller in the tilled plots, but appears to fall within the variability observed in the reference plots over time for all three, whether tilled or not (**Figure 4a**). Tilling and lime amendments appeared to have little long-term effect on soluble copper. The copper concentration increase in the North and East amendment plots was not persistent relative to their reference plots, as illustrated by **Figure 5**, which shows the difference between the reference and treated plots significantly reduced to near zero by 2013[20]. This change is a result of the North and East reference plots having higher soluble copper concentrations in 2010 and 2011 than the amended plots (though it is unknown if that was true in early 2008 before amendments were applied). These levels in the North and East reference plots have since been decreasing (significantly for the East reference plot), in contrast to the North and East amendment plots, which are not decreasing in soluble copper. Therefore, the two trends are converging to no difference (see **Figure 4a**). The effect of tilling on soluble copper is evaluated in other ways in the uncertainty section (Section 7.3.2), which also support no effect of treatments in decreasing soluble copper.

Possibly, the initial increase in soluble copper was from the addition of manure in June 2008, which is an abundant source of dissolved organic carbon. The temporary increase in soluble copper could be due to copper complexation with dissolved organic carbon. Free cupric ion activity did not concurrently increase (as seen on North and East amendment plots, which increased in both pCu and soluble copper right after the amendment, see **Figures 4a** and **Figure 4b**), likely due to free cupric ion complexation with the lime. The Northeast amendment plot, with the most organic matter applied (72 t/ac), exhibited a strong increase in soluble copper concentrations initially after organic matter application but within the range of variability observed on its reference plot (**Figure 4a**)**.** Surprisingly, TOC was not significantly higher in the Northeast amendment plot than in the adjacent reference plot (P = 0.385; see **Table 11**), even though very large amounts of organic matter were spread on the site. This supports that the soluble copper concentration increase may be a random fluctuation because organic matter may not have mixed in well with the soil without tilling and was lost in runoff.

Though soluble copper concentrations and pCu were inversely correlated in surface soil samples (r = -0.80; P <0.0001; n = 141), pCu is more directly related to the free cupric ion taken up by plants than soluble copper (which can occur in forms that are not taken up). Therefore, soluble copper was not used to establish target success criteria. Rather, because the mean value of pCu changed in the hypothesized direction

---

[20] The Northeast plot also trended toward a reduction in the difference between amendment and reference plots, but its high variability made the trend insignificant.

after amendments and tilling (though not significantly), pCu was the metric selected for target success criteria.

5.2.5 Hypothesis No. 5: Amendment of organic matter will increase TOC percentage and decrease C:N ratio; these changes will persist, meeting the target of 1% TOC and C:N of less than 20:1, preferably between 8:1 and 15:1.

The hypothesis for initial effects was supported for TOC after 1.5 years after amendment application. TOC significantly increased in plots amended with organic matter (P = 0.020) by an average of 0.38 percent (see **Table 10**) after almost 2 years (increase was slightly less after 6 months). The increase persisted or, in the case of the Northeast amendment plot (which had the highest amounts of organic matter applied), continued to increase (see **Figure 4b**). Average TOC also was significantly higher in the North and East amendment plots than in adjacent reference plots from 2010 to 2013 (see **Table 11**), and the difference persisted (see **Figure 5**). Post-amendment, the Northeast plot tended to exhibit higher TOC on average than the adjacent reference plot since 2010, particularly in 2013; although, as mentioned in the previous subsection, not significantly higher due to high variability of TOC on both plots (see **Table 11** and **Figure 4b**).

As mentioned previously, the steeper slope caused the organic matter to wash down the slope when it was spread during spraying of the lime, creating uneven application of organic matter compared to that for the more level North and East plots. All plots met the criterion of at least 1 percent TOC in fall 2013, indicating that the amendments and then plant establishment or recovery, with the new plants adding new organic matter over time, was effective at increasing carbon levels. The added TOC not only increases nutrient- and water-holding capacity of soils, but may further bind copper, possibly contributing to the increase in pCu observed with the decrease in pH. However, soil data are too limited to positively identify this condition, and other results discussed in this report suggest that the organic matter contribution to reducing bioavailability of copper to plants was limited.

The North amendment plot gain in TOC was persistent (change over time was not significant). However, if the last TOC estimate in October 2013 (see **Table 4**) indicates that the gain in TOC is possibly starting to be lost (or may be a result of variability in sampling). Nonetheless, because its TOC was already relatively high before treatment in May 2008 (1.25 percent), organic matter may not have been needed to increase TOC on the North plot, based on these TOC estimates in April and October 2013 . The value of adding organic matter is uncertain, and may be best for plots that are not on a slope and that exhibit <1 percent TOC.

Similar to TOC, the C:N ratio significantly decreased 1.5 after amendment application (P = 0.04, see **Table 10**). The C:N ratio was not related to amount of organic matter applied because it was significantly lower (by 3 or 4:1) in the amendment plots that received the highest and lowest organic matter applications (Northeast and North plots, respectively) than their adjacent reference plots (see **Table 11**). The increase in TOC was greatest in the East plot, which fell in the middle of the range of t/ac added (47 t/ac). However, the difference from the reference was small and not quite significant for this East amendment plot (P = 0.085; see **Table 11**).

The C:N ratio started out high before application, averaging 18:1 on the three plots (based on least square means; see **Table 10**). It dropped to 13:1 at 1.5 years after application. The organic matter added to the plots had higher C:N ratios (25:1, see **Appendix C-3**) than the upper threshold target of 15:1; therefore, the ability of the manure to lower C:N ratio may seem counterintuitive. However, the carbon and nitrogen in manure is highly labile and easily used by microorganisms, which respire off the carbon and retain the nitrogen, actually lowering the C:N ratio in the soil. All amendment plots met the optimum criteria of C:N between 8:1 and 15:1 in fall 2013 except the East amendment plot, which fell below the lower threshold to a 7:1 ratio (see **Table 4**). If the ratio drops too low, excess nitrogen is not used by bacteria or plants, but is volatized and lost from the system. The organic matter application rate of 47 t/ac for the East plot probably was too high.

Since amendment application, the C:N ratio has been further decreasing over time (see **Figure 4b**), though not more than reference plots. In fact, differences between the two were closer to zero by 2013 (see **Figures 4b** and **5**). All of the untreated reference plots exhibited C:N ratios within the target range by 2013 (see **Table 4**), though they were higher on average than those of the amendment plots. The C:N ratio in reference plots is steadily improving, possibly due to better plant community development after the white rain. These results suggest that organic matter application may not be necessary to improve soil nutrients for plant growth, although it can boost organic carbon and organic matter, which build better soil structure for retaining nutrients and binding copper. The addition of organic matter not only increased TOC, as shown by the correlation of $r^2 = 0.714$ between amount added and average increase in TOC from May 2008 to 2013 (n = 4), but also increased plant available nitrogen (ammonium and nitrate ions) and total nitrogen over time (see **Appendix C-11, C-12**). The organic matter added appeared to contribute to and facilitate the increase in the supply of nutrients (see **Appendix C-11, C-12**), except in October 2013, when the surface soil nitrates dropped to very low levels again in the North and East amendment plots.

5.2.6 Soil Data Variability

Spatial heterogeneity in soil parameters can be high, as seen by comparing results from sampling the same reference location at the same time using two different sampling methods (**Table 12a**). Surface soil pH and total copper were also being sampled for the Amendment Study reference plots using pH monitoring program protocols since 2010. Specifically, random sampling was used for the Amendment Study to capture the average condition in the each plot. The pH monitoring program used composite sampling in a plot that extended beyond the reference plot (2.6 times larger area sampled) but sampled in similar locations (four corners and center of plot) each year, shifted in a random direction by 5 meters each year (e.g., Arcadis 2014). Using the two different sampling methods on the reference plots at the same time from 2010 to 2013, differences in pH, total copper, and pCu can vary up to 37, 86, and 46 percent, respectively (see **Table 12a**).

Repeatability of results based on comparisons to field duplicates indicates that copper and pH met the Quality Assurance Project Plan (QAPP) standard (reference) of having the relative percent difference between the original and parent duplicate of 50 percent or lower for most of the samples. The soil pH and pCu always met these criteria, but copper did not for 13 percent of the fall samples in 2012 and 2013 (**Table 12b**). If the white rain had not happened, the quality of the data, despite its high variability for copper, may have produced enough power to detect large differences expected from the treatments. In fact, large differences in pH and pCu from the white rain were statistically detected, indicating that the data were adequate to detect meaningful changes. However, small changes expected after the white rain cannot be detected with much confidence given the variability in the data.

5.2.7 Subsurface Soil Trends

The purpose of the subsurface sampling, as stated in the Work Plan, was to monitor the downward migration of amendments through the soil column to address concerns that the lime addition will infiltrate downward with precipitation. If lime is leached from the surface soils, it may not be effective at increasing pH in the shallow soil in the long term. The persistence results in Section 5.2.1 of this report and in the white rain report (Arcadis 2017a) support that an increase in pH in the shallow soil from the white rain and liming has persisted for at least 5 years. The effect of lime added to the surface soil in the tilled plots on pH does not appear to be lost with precipitation in a 5-year period. The persistence beyond 5 years is uncertain, though the ABA results and high pH in all the plots (>5.5) show promise of continued persistence, as discussed earlier.

Though short-term persistence in the surface soil pH has been supported, the subsurface pH data can further reveal if copper or acidity have changed over time at depth in the lime-treated plots due to the migration of lime (or hydroxide ions) or cupric ions after treatment. **Appendix C-13** demonstrates that the positive relationship between surface and subsurface pH is not very different between treated and untreated plots, except that the untreated plots have more variability in the relationship, making the relationship not quite significant. The positive but shallow slope of the relationship suggests that some acidity from the smelter may have migrated deep enough to affect the lower soil layer during the century of smelter operation, but to a limited extent. The surface pH is still significantly lower than in the subsurface soils (6.3 vs. 7.2, P <0.0001), indicating that the surface soil (0- to 6-inch depth) is the main location of pH impacts from the smelter. It is also the layer that changed from treatments because the difference between layers is reduced in the North and East tilled plots post-treatment compared to the pre-treatment plots and post-treatment untilled plots due to an increase in pH in the treated surface soil (**Appendix C-14)**. The East plots exhibit the greatest reduction (surface and subsurface layers became more similar in pH; **Appendix C-14**), but that may be because subsurface samples were not as deep in the East plots as in the North plots (see below and **Appendix C-4).**

The trends support the results in **Section 5.2.1** showing that pH in the shallow soil in these tilled plots increased after the amendments were tilled into the soil. The Northeast plots do not show a reduction between surface and subsurface soils, possibly because of runoff on the steeper slope removing lime that was not tilled into the soil. The West control plots do not show much stratification in pH with depth (both layers exhibit high pH) because of the surface soil's high buffering capacity maintaining a pH similar to the deeper strata. In conclusion, pH in the subsurface did not significantly increase between the pre- and post-treatment periods, indicating very little downward migration of lime into the deeper layers below 12 inches bgs during the 5 post-treatment years of the study.

For copper, concentrations are higher in the surface than in the subsurface soil, as expected. Though variable, there is no obvious trend over time in the treated plots of copper slowly decreasing in the surface and correspondingly increasing in the subsurface layer (**Appendix C-15**). Therefore, copper does not appear to be migrating into deeper layers during the study period. However, the relationship between surface and subsurface copper was steeper in treated than in untreated plots (**Figure C-13**), mostly due to a few Northeast plot subsurface samples that were high in copper. If two subsurface samples exceeding 1,400 mg/kg of copper in the Northeast amendment plot in October 2009 and October 2013 were removed, the slope of the regression is almost identical to that of the untreated plots and indicates no relationship between surface and subsurface soil concentrations.

Soils on steeper slopes experience more erosion and accumulation of colluvium near the slope bottom via gravity[21], which may create more heterogeneity in subsurface chemistry profiles. Though concentrations higher than 1,000 mg/kg were not found in the similarly steep-sloped Northeast reference plot, fewer years of data were obtained in that plot; the more limited sampling may have missed some of the higher copper concentrations in the subsurface. The low copper in the subsurface in untreated plots may indicate that, over the years of smelter operation, copper may not have migrated downward, and is not as mobile as the hydroxide ion. Overall, migration of copper and acidity downward during the relatively short 5-year period after treatment appears to have been limited, with the main effects occurring in the surface layer.

The limited migration of cupric and hydrogen ions over a 5-year period also indicates that the hard pan clay layer did not play a major role in the effect of treatments on the soil chemistry. The clay hard pan was most often below 12 inches (**Appendix C-4** shows that maximum depths of samples, which were controlled by hard pan refusal, were never shallower than 12 inches). As concluded above, this depth probably was not reached by migrating acidity and copper ions during the study. Also, the tilling was only to 8 inches and thus avoided breaking up the hard pan layer. The only minor effect of the hard pan was on pH samples of the subsurface because the maximum depth of the subsurface samples often was controlled by the hard pan.

A "subsurface sample" was not always at the targeted 18- to 24-inch depth because of refusal at the hard pan layer before reaching 12 inches. The maximum depth of subsurface samples had a small positive significant effect on pH of the subsurface samples, where r^2 of linear regression was 0.16 (Northeast, P= 0.03), 0.26 (North, P=0.004), and 0.34 (East, P = 0.0007) for the four amendment plots. The maximum depth of these subsurface samples had no effect on copper (r^2 ranged from 0.02 to 0.11, P>0.05). The hard pan is deeper in the North plots than in the East plots (**Appendix C-**

---

[21] Surface layers may have been buried as soil is eroded downslope and now are subsurface layers that still have surface concentrations.

4), and as such, the effect on pH is greatest in the East plots. Therefore, the effect of the variable depth sampling on pH but not copper likely explains why the difference between surface and subsurface samples for pH are smaller for the East plots than for the North plots, and this pattern is not observed for copper. This is considered in the interpretation of the results above.

5.3 Effectiveness of Amendment/Tilling at Improving Vegetation Community

The change in soil chemistry from amendments and tilling was expected to affect the plant community in terms of bioavailable copper, uptake of copper, and plant cover, and eventually increase species diversity measures (quantified as Shannon diversity, Shannon evenness, and richness). The improvement should change species composition, allowing more species beneficial to wildlife and livestock to thrive. However, because the plots were disturbed by complete vegetation removal followed by tilling, or by lime and organic matter temporarily covering plants in the untilled plot (Northeast amendment plot), vegetation re-establishment and/or recovery were evaluated before determining if the plant community changed. Of note, succession in semi-desert systems takes much longer than 5 years (Romme et al. 2003; also see **Appendix B-3**), and overall benefits in terms of species richness and cover from the treatment may not be evident within the 5-year time frame of this pilot study.

To address effects of the remediation technologies on the vegetation, the following sub-sections evaluate

- Section 5.3.1: Success of the vegetation re-establishment and recovery
- Section 5.3.2: Plant uptake of copper
- Section 5.3.3: Effects of the treatments on cover, diversity, and species composition from the reduction in pCu.

5.3.1 Vegetation Establishment

Although it was not the goal of this study to evaluate closure potential with regard to reclamation success guidelines prepared as part of the CCP, several vegetation parameters were evaluated with respect to these guidelines. Chino recognizes that the CCP success criteria were created based on long-term goals with expected vegetation community conditions equivalent to those produced over 12 years of succession. These conditions would correspond to those found after a 12-year bond release period. Data evaluated in this report reflect a more early-successional stage vegetative community present 5 years after remediation. Therefore, the success criteria are intended to be applied to this project only as a benchmark for evaluating progress of the restored plant communities toward the CCP success criteria after 5 years in relation to changes in copper uptake by plants. In addition, vegetation cover was evaluated over the short term to assess and control the risk for erosion caused by the amendment/tilling procedures.

5.3.1.1 Short-term – Erosion Risk

The criterion for the short-term goal of vegetation re-establishment was defined as native cover that is 70 to 100 percent of the average percent native cover of adjacent reference plots. The exact amount of native cover that resulted was uncertain because one species of bristlegrass that colonized the East amendment plot could not be identified to species with certainty and may have been a non-native annual grass (*Setaria viridis*) or a native, perennial bristlegrass (*Setaria leucopila*). Both are known to invade disturbed areas. For this report, it was assumed to be a native perennial because the perennial is common in mesquite areas in the Chino area. Under that assumption, this criterion was met within 2 years and sustained during the vegetation sampling periods since October 2009 (**Table 13**). Even if the bristlegrass was the non-native species, the criterion was still met within 2 years and sustained. These results indicate that, within a short period of time, the vegetation recovered naturally (without a seed mix) to an extent that limits erosion problems.

5.3.1.2 Longer-term – CCP Protocol

Based on CCP quadrat data (collected in October 2010 and October 2013), CCP criteria were met in 2013 in all amendment plots including the undisturbed control plot (West plot), except for cover by cool-season grasses, shrub density, and number of shrub species (**Table 14**). Cool-season grasses also did not grow on the unimpacted Tailing Pond site used to develop the criteria; therefore, it is unlikely that the cool-season grass criteria could be met without seeding these species. Moreover, it is likely that cool-season grasses will only be a minor to possibly absent component in a later successional stage of these sites because they are not common in the mixed herbaceous grama alliance or mesquite/mixed grama alliance of these communities, as characterized in the Comprehensive Vegetation Survey of Chino Mine (Daniel B. Stephens & Associates 1999) and in the site-wide ERA (Newfields 2005).

Although the shrub cover criterion was met in all plots after 5 years, shrub density and number of shrub species (shrub richness) did not meet the CCP success criteria of 0.5 shrub per square meter (m^2) and two shrub species for the tilled North and East amendment plots (see **Table 14** and **Appendix B-4**). This indicates that the development of multiple strata to provide greater structural diversity for wildlife habitat is still in progress, particularly in the East amendment plot. The North amendment plot is closer to the density success criteria, with 0.3 shrub per m^2, compared to very few shrubs on the East amendment plot (none recorded on transects). For both plots, only one shrub species (honey mesquite) was represented on the CCP transects. Although these CCP criteria have not been met on the CCP transects, additional shrub species were present in both the East and North amendment plots on the circular 0.01-acre plots, indicating that shrub species are colonizing the plots. The East amendment plot had three shrub species in 2013 (saltbush [*Atriplex* sp.], Yerba de pasmo [*Baccharis pteronoides*], and honey mesquite), while the North amendment plot had two shrub species (soaptree yucca [*Yucca elata*] and honey mesquite; see **Table 15**). Unlike the tilled plots, the untilled Northeast amendment plot easily met the shrub density and richness criteria, as expected because shrubs were not destroyed during application of the remedy.

The lower density of shrubs in the North and East amendment plots relative to the untilled Northeast plot is due to clearing and tilling that removed shrubs, which resulted in high cover of early successional annuals on the North and East plots (see **Figure 8**). The North amendment plot had a surprisingly high (20 percent cover), though stunted, amount of mesquite shrub cover after only 6 months; this is likely a result of re-sprouted mesquite root masses that remained due to the ineffectiveness of tilling to 8-inch depth at destroying the deeper mesquite root masses (see **Table 15**). In contrast, tilling was very effective at destroying shrubs on the East plot, which has averaged only approximately 3 percent mesquite since tilling. The East plot soil is shallow and probably did not support as deep-rooted mesquite. Successional patterns in other semi-desert areas without chemical impacts suggest that, as perennial grasses and forbs become established after about 20 years, annuals will be displaced, and a greater cover by perennial forbs and grasses (as well as density of shrubs) will become more prevalent (Romme et al. 2003; **Appendix B-3**). Shrub density and cover are expected to increase over time, and will likely meet the CCP criteria within the time frame set up by the CCP guidelines of about 12 years.

More detailed information pertaining to the vegetation community re-establishment after disturbance and expected successional patterns is provided in **Appendix B-3**. Overall, the results suggest that the amended plots are meeting the criteria of: (1)

colonizing with a diversity of native species with a low proportion of exotic, invasive species (see **Figure 11**), (2) progressing in the development of horizontal and vertical complexity important to wildlife habitat, and (3) increasing by 2013 to high levels of cover (**Figure 9a)** and low amounts of bare soil (**Appendix B-5**). The plots had disturbance and manure added, however, which may have allowed more aggressive annual forbs (and some annual grasses) to increase and dominate the tilled plots by 2013 (see **Figure 8**) and resulted in a loss of overall grass cover on the untilled Northeast amendment plot (see **Figures 13a, 13b,** and **13c**).

None of the invasive species on the list for New Mexico (**Appendix B-18)** were identified in any of the plots of the Amendment Study. If tillage and disturbance occur on a large scale with large barren areas, it is possible that tillage and plot disturbance will initially increase the number of invasive species. Disturbed areas are subject to greater invasiveness than non-disturbed areas. Tilling and other disturbance can increase resource availability (e.g., growing space, light, or nutrients) by removing plant cover or freeing nutrients that would be consumed by other plant species (Davis et al. 2000). Burke and Grime (1996) found that invasiveness was strongly related to the availability of bare ground, which would be greatest immediately following disturbance. Propagules of native species growing nearby will also become established and over time will outcompete weedy early successional species as the plots transition through successional stages. It is unknown what the impact on vegetation composition will be and for how long if tilling is implemented at a large scale. At a small scale, invasive species were not a problem.

Despite the plots not having been seeded, vegetation re-establishment to conditions similar to those before disturbance appears to be on an expected trajectory toward eventual recovery. However, return of life forms in proportions observed before the disturbance is still far from recovery. As discussed in **Appendix B-3**, the establishment patterns observed on the tilled plots of increasing domination by annual forbs over the first 5 years are typical for plowed fields. Additionally, the reduction in grasses observed on the Northeast amendment plot should shift over time with the eventual return of these species. Overall, the dominance of perennial species present before amendments were applied may take a long time to recover on these plots, over many decades (see **Appendix B-3**), but should eventually occur. In fall 2014, after this amendment study was completed, some weedy annuals decreased in abundance, and these conditions were sustained in 2016, looking very similar to those in 2014 (see photolog in **Appendix D** showing carelessweed (*Amaranthus palmeri*) dominance greatly reduced except still abundant in the North tilled plot). As discussed in detail in Section 5 of **Appendix B-3**, vegetation succession has been set back in each of the treated plots, and recovery to a mature, healthy plant community may take at least 50 years.

The question remains whether the increase in pCu from the white rain and remedial technologies (amendments and tilling) reduced copper uptake in plants and improved the vegetation community as habitat for wildlife and livestock. That question is addressed below in Sections 5.3.2 and 5.3.3 with two hypotheses. The additional time needed for the vegetation communities to mature is considered in the analysis.

5.3.2 Hypothesis No. 6: The increase in pCu from lime, organic matter, and tilling will reduce uptake of copper into plant tissue.

Based on the results of the test of hypothesis 3, soil pCu did not significantly increase from the combination of white rain, lime/organic matter, or with tilling added, at least not with high statistical confidence. Given that finding, this hypothesis does not need testing because no increase occurred. However, power to detect statistical differences in pCu was low (Section 7.2), and this result is highly uncertain because the mean pCu was higher in amendment plots after treatment, particularly the tilled plots (**Table 9a**). The tilled plots exhibited higher pCu after treatment but only with 80 percent confidence. If an actual increase did occur, the higher pCu may have resulted in reduced plant uptake of copper. Plant concentrations of copper were inversely correlated to soil pCu but not quite with statistical significance ($r^2 = 0.28$, $P = 0.07$, see **Appendix B-6, B-7**). The hypothesis that the amendments and tilling reduced copper uptake can best be evaluated by comparing the reduction in plant tissue concentrations by the white rain event in January 2008 (discussed earlier under hypothesis 1 in **Section 5.1**) to reduction in concentrations by both the white rain and amendments/tilling (see **Figure 6**, and **Tables 7** and **8**). If the results also show no change in uptake due to treatments, support is strengthened that the treatments provided no additional benefit once the white rain had increased pCu.

It is difficult to separate the early effects of white rain from lime and tilling effects by comparing tissue concentrations before and immediately after amendment application because no copper concentrations representative of post-white rain tissue before amendment application are available. The plants sampled in March 2008 on the amendment plots (none were sampled on reference plots in 2008) were dormant (old leaves), not growing new leaves in the winter. Therefore, the plants represent pre-white rain conditions because the white rain event was in January 2008 after the growing leaves accumulated copper. Deciduous shrubs had not yet put on leaves (which is why mesquite was not sampled in 2008). Therefore, as discussed previously, plant tissue concentrations from March 2008 were considered pre-white rain estimates.

To evaluate the effect of treatments alone, rather than combined with white rain, several steps were required. First, the pre-treatment amendment plots were compared to reference plots in 2013 after the white rain (see Section 5.1) to identify the effect of the white rain on mean tissue concentrations. Second, the pre-treatment amendment plots were compared to post-treatment amendment plots in 2013 to identify the combined effect of treatments plus white rain. Third, the effect of white rain alone was subtracted from the effect of white rain and treatments combined, which is the reduction in tissue concentrations that resulted from application of the treatments alone (**Table 7**).

Another way to evaluate the treatment effect and reach the same result is to subtract the mean tissue concentration of the untreated post-white rain reference plot from the adjacent treated post-white rain amendment plot[22]. Both methods assume that the white rain affected both plots equally, and the difference in tissue concentrations is mainly from amendments and/or tilling, not from inherent differences in the soil or original concentration of soil copper among the adjacent plots.

Figure 6 shows the reduction in tissue concentrations (washed) from the white rain and white rain plus treatments with and without the dormancy bias adjustment. With the dormancy adjustment, the reduction from the treatment alone (after removing the white rain effect) is statistically significant (significance set at $P < 0.10$ due to low sample size), but only for herbaceous vegetation (when mesquite is removed, $P<0.09$, bottom analysis in **Table 7**). Tissue concentrations in the treated plots were reduced by 7 mg/kg in the herbaceous vegetation. If the less sensitive but high copper-accumulating species of mesquite is included, the difference is 12 mg/kg (also see **Figure 6**); however, that difference is no longer statistically significant (**Table 7**). The white rain reduced concentrations by up to 60 mg/kg (**Table 7**) and as such, had a much larger effect. The small effect from the treatments is not unexpected given that

---

[22] This second method produces same final result (**Table 7)** because no difference could exist between concentrations in amendment and reference plots pre-treatment/white rain, given there was no reference plot in May 2008 for soil sampling, and the first method substitutes the amendment plot for the reference plot during that period.

the white rain had already neutralized a considerable amount of acidity. Unlike the tilled plots, the Northeast plot (which was only limed, not tilled) did not exhibit a reduction in copper in the plant tissue (0 difference, **Table 7**). The two plots that responded with a reduction in uptake (North and East plots) were on relatively flat ground and tilled. Tilling of lime into the soil on flat ground that limits runoff may improve effectiveness.

After the white rain and treatments, the final tissue concentration average in the North and East plots in 2013 was low at 18 mg/kg (washed)[23], no longer high enough to be of great concern because it falls within the range of nutritional sufficiency (Schulte and Kelling 1991) for copper and below phytotoxicity levels tissue toxicity thresholds (McBride 2001), though higher than background concentrations observed off the mine site near the airport of 8 mg/kg on ERA reference plots in 1999 (see **Figure 6**). When mesquite was removed, the tissue copper concentration averaged even lower at 13 mg/kg (**Table 7**). As mentioned above, the Northeast plot did not improve with addition of lime and organic matter and still exhibited high tissue concentrations in 2013 of 34 mg/kg (**Table 7**). The lack of a response in the Northeast plot is consistent with the results, showing that pH increased the most (and almost significantly) on the tilled and amended relatively flat plots, but not in the untilled Northeast plot.

The estimates of copper reduction from treatments assume that tissue concentrations were the same before treatment in the reference and amendment plots. However, for the three plots, the pCu was estimated to be about 8 percent lower in reference plots than in amendment plots before the amendments were applied (**Table 1**[24]), which, using the bioaccumulation equation for amendment plots in **Appendix B-7**, could account for 6 of the apparent 7 mg/kg “reduction” in tissue concentration observed. This means that most of the reduction did not occur from the tilling and amendments because it can be attributed to inherent differences between the amendment and reference plots. This result is consistent with the conclusion in Section 5.2.3 that, after

---

[23] See **Appendix B-16** values for North and East amendment plots in 2013, multiply by 0.9282 to convert to washed and average to obtain 18 mg/kg.

[24] Pre-treatment (but after white rain), amendment plots averaged a pH of 4.14 (North = 4.31, Northeast = 3.50, East = 4.61) vs. 3.81 for reference plots (North = 4.43, Northeast = 3.41, East = 3.59).

the white rain, the amendments and tilling provided little additional benefit in pCu relative to the reference plots after 5 years.

The white rain alone reduced copper uptake into aboveground plant tissue by an average of 36 mg/kg in the North and East amendment plots and by 60 mg/kg on average when the Northeast plot was included (**Table 7**). The 36 mg/kg reduction is commensurate with the average pCu increase by 1.7 s.u. in the two plots (North and East) from the white rain (bioaccumulation model predicts a 32 mg/kg change in tissue copper with pCu change of 1.7).

The lack of significant change in pCu from additional liming with organic matter and/or tilling after the white rain already increased pCu is consistent with the interpretation of the tissue concentrations that the treatments did not reduce copper uptake into the plants, or if a reduction occurred, it was very small (1 mg/kg), and only in herbaceous plants. However, the decrease in copper in plant tissue, whether from the white rain only or from the white rain combined with some minor liming and tilling effects, was nonetheless beneficial in the relatively level plots because the concentrations in these plots fell below the high end of the nutritional sufficiency range for copper.

Uptake of copper varies depending on the plant species, which introduces uncertainty into the conclusions on limited or no effectiveness of the treatments on copper uptake. A reduction in copper in plants could occur in the root tissue and be missed in the shoot tissue for species that are excluders of copper (rather than accumulators, Baker 1981, Tilstone and McNair 1997) and do not translocate much copper from the root to the shoot. In general, a decrease in bioavailable copper (cupric ion) produces lower copper concentrations in shoots, but the relative amount may vary by species (Korzeniowska and Stanislawska-Glubiak 2003, Sheldon and Menzies 2004, Verdejo et al. 2015). Soil pCu may be constant in a soil but produce variable copper uptake responses in individual species. The toxicity of the copper in the tissue also will vary depending on the species tolerance (Tilstone and McNair 1997). For this reason, community response endpoints are the best indicators of the effect of pCu changes on toxicity, better than the tissue concentration endpoint.

Community responses measured in the field also account for variability in uptake as a result of variability in the chemistry of the in situ soil. The Terrestrial Biotic Ligand Model indicates that other ions in the soil (H+, Ca^{2+}, and Mg^{2+}) compete with Cu^{2+} for ligand sites of the root and reduce copper uptake (Thakali et al. 2006). Toxicity is more correlated with the fraction of ligand sites actually occupied by Cu^{2+} than pCu (Verdejo et al. 2015), which is why community variables must be evaluated to identify if there has been a toxic response to changes in pCu or tissue concentrations. The next section evaluates the effect of treatments on community variables.

5.3.3 Hypothesis No. 7: The reduced uptake of copper will increase canopy cover and richness. It will also increase evenness and overall diversity of the plant community by 2013 and change the community composition.

5.3.3.1 Plant Cover and Diversity Measures

As stated in the previous section, reduced uptake of copper into plants from any of the remedial technologies is highly uncertain, with the best estimate being at most a 1 mg/kg reduction in the herbaceous vegetation of the tilled plots. The hypothesis being tested for this section-- that reduced copper uptake from the treatments will increase canopy cover, richness, evenness, and overall diversity---depends on having met the condition that copper uptake into plants was reduced. If treatments were ineffective because the white rain already changed the pCu, and as a result reduced uptake and improved the community composition, then any additional changes observed in the community from the treatments after removing the effect of the white rain would not be due to chemical improvements but rather due to four physical factors produced by the treatments: (1) destroying the vegetation during tilling and re-starting succession; (2) disturbing vegetation in untilled areas by driving over plants and spraying them, setting the plot to an earlier stage of succession; (3) decompacting poor rangeland soils with tilling; or (4) adding organic matter that structures and enriches the soil, favors different species, and may contain weed species newly introduced to the area.

Because it is uncertain if treatments were effective in changing copper bioavailability to plants, community changes in the treated plots may provide insight into their possible effectiveness. Changes observed were identified after removing effects attributable to the white rain and climate. The change in vegetative pre-white rain conditions sampled in March 2008 to post-white conditions sampled in October 2013 on the reference plots represents not only the white rain effect, but also the differences resulting from climatic changes between those two periods. If changes from the treatments in the amendment plots (after subtracting white rain/climatic effects) appear commensurate with expected changes based on the treatment's chemical effectiveness and not the four physical factors listed above, the data may indicate positive chemical effects. Such effects may have been missed in the statistical analyses for soil and copper uptake because of lack of power in tests or lack of adequate reference areas. Examples of expected changes from chemical improvements are an increase in grasses, non-woody vegetation, species diversity, or richness in soils that do not have properties limiting plants physically (e.g., by compaction). Also, grass and other species associated with high pCu (based on an ordination technique discussed below) should become more abundant in treated plots. However, if changes in the vegetation community can be solely ascribed to the four factors based on evidence in the literature, from the ordination, and from other studies and analyses in the STSIU (e.g., the discussion in **Appendix B-21**), then the results would support the conclusion that the remedies applied in this study were not effective at remediating chemical impacts.

To identify treatment effects regardless of whether they are chemical or physical, the white rain and climate effect (hereafter referred to as white rain effect) was first identified by comparing seven vegetation measures (cover, richness, evenness, Shannon diversity, non-woody cover, grass cover, and annual cover) before (March 2008) and after (October 2013) the white rain in the reference plots. The same comparison was made for the amendment plots to assess the effect of the white rain plus treatments. The difference in these two comparisons provides insight into the effect of the treatments (**Tables 16a** and **16b**). The community data comparisons were insufficient for a statistical analysis (sample size of one in reference plot each sampling period and two for amendment plots), so the analysis is a qualitative comparison of estimates. However, if the difference due to the white rain in reference plots or due to the white rain plus treatments in the amendment plot appeared to be small relative to the variability in the trend of the vegetation characteristic over time on **Figures 8, 9a, 9b,** and **10** (tested with a one-sample t-test between pre-amendment value and mean of post-amendment values in **Appendix B-20a** and **20b**), the difference was assumed to be unimportant or uncertain.

The differences in total cover, richness, evenness, and diversity between the amendment and reference plots, rather than absolute values for the amendment plot, were also evaluated graphically on **Figure 11 (**see **Appendix B-3)**. The difference[25], was examined to reduce the effect of seasonal and annual climatic differences when comparing the pre-amendment period (which is in spring) to the post-amendment periods (which are mostly in fall). Both the reference and amendment plots were subject to the same climatic conditions and thus differences between the two types of

---

[25] Difference between amendment and reference lines on **Figures 9a** and **9b**.

plots should reflect differences from treatments applied, not from precipitation or weather[26]. This assumption is investigated more thoroughly in Section 7.9.

Effect of White Rain. The white rain may have increased species richness because all the reference and control plots showed increased richness after the white rain (**Table 16a, Figure 9b**). Even considering climatic and seasonal differences, richness was still higher because the spring 2008 results were lower than the spring 2010 results, despite spring 2010 having a slightly drier growing season than the growing season for March 2008 (**Figure 16**). Shannon diversity also increased, but one plot did not exhibit the increase (Northeast reference plot, **Table 16a, Figure 9a**). Evenness increased only in half the plot locations. Percent cover did not change with any certainty in most of the plots except the Northeast reference plot, which exhibited a decrease in cover after the white rain[27] (may not be related to white rain because it exhibited smallest change in soil pH of only 0.5). The proportion in non-woody cover increased in all but the West control plots (**Table 16b**). West plots already had high pCu before the white rain, however, and their response may not be that informative. The change in proportion in grasses after the white rain was uncertain or absent for more than half the plots and showed a minor increase (Northeast plot) or decrease (one West control plot) in the other plots. The change in the proportion in annual species was inconsistent, either uncertain, an increase (North), or a minor decrease (East). White rain effects on vegetation are evaluated using other data sources to confirm these conclusions in **Appendix B-21**.

Effect of Treatments. After subtracting the white rain changes listed above, changes observed from the treatments included an increase in the total vegetative cover in the Northeast and East plots and a decrease in evenness in the North plot (**Table 16a**). The proportion of the total cover in grasses decreased in the Northeast and North amendment plots, but increased in the East amendment plot (**Table 16b**). The proportion in non-woody species also increased in the East plot, with a minor increase in the North plot (mostly due to annuals), and any change in this measure was uncertain in the Northeast plot. Annual species increased in the tilled plots (North and

---

[26] Similar to above, where white rain and climatic effects are removed by the difference in the reference plots between October 2013 and March 2008.

[27] The North reference plot exhibited an absolute increase in total cover of 25 percent, but that level of increase falls within range of variability of cover.

East) and changes in annual species were uncertain in the untilled Northeast plot (**Table 16b**). The changes in evenness and richness were too uncertain in all the plots falling within variability of these measures over time (**Table 16a**).

The decrease in grasses in the North and Northeast amendment plots and loss of total cover in the North amendment plot from the treatments are of concern because the objective was to improve grass cover. The decreases likely are because these plots were in fair rangeland condition and the disturbance from tilling or spraying with lime and depositing organic matter on the plants transitioned the plots to a more degraded condition and earlier successional stage (see **Appendix B-3, Section 5**). In contrast, the East amendment plot had been in poor rangeland condition, and decompacting the soil may have been the factor that increased grass cover. The photographs of the soil just after being tilled (see **Appendix D**) demonstrate how rocky and poor the soil was on the East plot compared to the finer, more granular soil in the North plot.

Figure 11 shows whether initial changes from treatments and white rain[28] persist over the next 5 years relative to the reference plot trends (trends are differences between the amendment and reference plots). For example, pre-treatment difference in cover of the East amendment plots is low before treatment and the white rain, but becomes high after and remains high (slope is not significantly different from zero) and therefore is persistent (**Figure 11**). The North and Northeast amendment plots have more cover than the reference plot, which is lost after treatments/white rain and not consistently and significantly regained (insignificant slope). The negative effect is persistent.

Diversity and richness loss is significantly regained in the Northeast plot, so the negative effect for those parameters is not persistent. All other trends on **Figure 11** do not show a significant lack of persistence. Sample sizes are probably too low to detect trends statistically for the other plots with a noticeable non-zero slope in the regression line. The high variability in the parameters over time makes conclusions of persistence in non-significant regressions on **Figure 11** less certain.

---

[28] If trends of the amendment plot lines on **Figures 8** to **10** and **12** are evaluated only, the trend represents white rain effects and climatic effects on top of treatment effects because March 2008 represents pre-white rain conditions (though for soil, it is post-treatment conditions). **Tables 16a** and **16b** subtract the white rain and climatic effects (called white rain effects in that table) to show the actual treatment effects, as does **Figure 11**.

Figures 9a and **9b** also show if the final plant community characteristic of the treated plots is much higher than the reference plots by 2013 or if both communities look similar at the end of the study. The results in those figures indicate that Shannon diversity and evenness of the plant community have improved to levels similar to the adjacent amended plots by 2013, indicating that strong departure from the reference plot condition in 2013 is minimal for those community parameters.

Table 16a is the most informative for interpretation of treatment effects alone on cover, richness, diversity, and evenness because it separates white rain and climate from treatment effects, incorporates variability on **Figures 9a** and **9b**, and accounts for inherent differences in the plots before the white rain or treatments because it evaluates differences over time within the same plot. **Figures 9, 10,** and **11** do not separate out the white rain (March 2008 is a pre-white rain community). The trends in plant community changes are discussed in more detail in **Appendix B-3,** and climatic effects on trends are discussed in Section 7.9.

The following section evaluates the remedy effects as to whether they caused more harm than good in some plots or were beneficial or likely to be beneficial in the long term to the plant community. First, changes in community composition relative to changes in soil chemistry and physical properties are evaluated. Species possibly responding to chemical rather than physical changes are identified. Then each plot is evaluated relative to those species to identify if remediation of the pCu might have benefitted the plant community.

5.3.3.2 Overview of Changes in Community Composition

The change in community composition relative to soil chemistry was quantified using an ordination technique. A CCA ordination was conducted on the plant community data for vegetation sampling events that yielded corresponding soil data. A CCA is a multivariate ordination method used to determine the relationships between plant communities and environmental variables (ter Braak and Verdonschot 1995). CCA accounts for variation in the community composition at each site that directly corresponds to the environmental variables included in the analysis. In this case, the environmental variables include the soil chemistry parameters (pH, pCu, copper, soluble copper) and physical parameters strongly affecting the communities. The physical variables included “time since disturbance”, tilling, and TOC. The time since disturbance variable provides information regarding the effect of successional processes on community composition. The disturbance variable was set to zero before amendments and on reference/control plots; it was set to the highest disturbance (5) immediately after amendment application and/or tilling and then decreased (from 5 to 1) for each sampling event thereafter to represent time since disturbance (see **Appendix B-8**) or the recovery trajectory. The tilling variable (tilled, not tilled) accounts for some plots having complete removal of vegetation, thus resetting vegetation succession completely. A summary of the statistics and variance explained in the CCAs is provided in **Appendix B-22**.

Biplots were created that illustrate the relationship between soil chemistry parameters and species with the West control plots included (**Figure 13a**) and without (**Figure 13b**) because the West control plots represent a different vegetation alliance (Newfields 2005). The arrows (direction of gradient) point to the direction of most rapid positive change in each environmental variable (negative change is in opposite direction of arrow). The length of the arrow (strength of gradient) is proportional to the correlation between the ordination and environmental variable.

The purpose of the CCA was to tease out the relationships between the chemical and physical variables and each species making up the community structure. Species that change in response to chemical parameters such as pH, copper, soluble copper, and pCu but do not respond to physical variables or organic matter content (represented by TOC) are of greatest interest. These species should increase in treated plots if soil chemistry and not physical factors are a key driver of the community composition. When vectors of environmental variables are at right angles to one another on the biplot, they are relatively independent, making interpretations easier than if they are more parallel, meaning they covary.

The biplot results provided on **Figure 13a** include all plots, including the West control plots. As might be expected, the sampling events cluster together in the first biplot based on: (1) the geographic locations of each sampling plot (North, East, Northeast, West), except that East and North locations are intermixed, and (2) amendment status (treated or not; **Figure 13a**). The biplot shows that the vectors for pH and pCu are almost parallel, indicating that they covary, whereas the tilling centroids (if connected by an imaginary line) and time since disturbance vector and are relatively independent of these chemical variables at right angles to pH and pCu. Species that occur in high pH or pCu areas are plotted near the end of the pCu and pH arrows of the second biplot (see **Figure 13a**). Species far in the opposite direction of those arrows occur in the low pCu and pH soils (arrows not drawn in opposite direction but would be the same length). The species preferring high pH include many grasses (red labels on bottom graph) on the West control plots, but these grasses also prefer less disturbance because they fall in the angle between low disturbance and high pH vectors (**Figure 13a**), making it difficult to identify if they are responding to disturbance or soil chemistry. The West control plots are driving this result because they are undisturbed and associated with high pH and to a lesser extent high pCu compared to the other three plot locations, as shown in the first biplot on **Figure 13a**.

Because the biplots on **Figure 13a** are so strongly affected by the high pH West plots, the West plots were removed from the biplots on **Figure 13b** to better identify treatment effects. The CCA without West plots produced environmental vectors at right angles to each other, representing time since disturbance and pH/pCu. Species falling along and near the end of either of one of these vectors represent species responding mostly to that vector. The TOC vector fell between these two axes (**Figure 13b**). Two variables difficult to separate on these biplots because they covaried were pH and tilling, which have vectors nearly parallel with the horizontal CCA1 axis on **Figure 13b.** Fortunately, **Figure 13a** can provide information for separating tilling effects from chemical effects, and **Figure 13b** can separate chemical effects from time since disturbance. For example, two species (CHVI = feather fingergrass [*Chloris virgate*], SESP = bristlegrass [*Setaria* sp.] see **Appendix B-9** for plant codes) appear to prefer high pH or pCu on **Figure 13b,** but **Figure 13a** indicates that they are responding to the tilling (colonizing tilled areas), which happened to be correlated to pH on **Figure 13b**. They are not strongly correlated to the chemical parameters on **Figure 13a**. Red threeawn (ARPU) is more consistent in that it grows often in high pH or pCu areas, as shown by both **Figures 13a** and **13b**, and disturbance may be less important to its presence. The literature supports this CCA result, indicating that red threeawn can occur abundantly in either early successional or climax stages (Clements 1916).

The environmental vector on **Figure 13b** that best separates East and North amended plot communities from their untreated reference plots is TOC (higher TOC in plots with organic matter added). The biplot showing that TOC is the main driver affecting the community in the early successional stage for tilled East and North plots is supported in the literature because disturbed soil with organic additions releases nutrients as represented by TOC. The bare ground invites fast-growing pioneering species to invade until later successional species that grow slower gain a foothold and can outcompete them for the nutrients (Davis et al. 2000). The initial pioneer species are weedy annuals, like Russian thistle (*Salsola tragus,* SATR; **Figure 13b**) and golden crownbeard (*Verbesina encelioides*), not perennial grasses. The combination of disturbance from tilling and TOC/nutrients from amendments facilitates dominance by these ruderal, colonizing species, which are often annuals. A decrease in disturbance over time and its soil nitrogen release should eventually result in a community increasingly dominated by more competitive perennial species.

In contrast, time since disturbance, not TOC, best separates the Northeast amended plots from their untreated counterparts. Despite not being tilled, the spraying of lime and spreading of organic matter (with backhoe) on the Northeast amendment plot caused some disturbance and community changes. The disturbance on the Northeast plot mainly degraded the complexity of the species composition initially and set succession back with loss of grasses and succulents (see Section 5 in **Appendix B-3),** while tilling as a disturbance set the successional stage back to the earlier simple Russian thistle dominated community in the first year for the tilled plots. These results indicate that surface disturbance in general, whether tilling or driving over plants, strongly influences community composition.

To identify if chemical changes are shaping the treated community composition, the percent cover of five indicator species discussed above was evaluated. The two grass species (feather fingergrass and bristlegrass) and the forb golden crownbeard associated with tilling and the early pioneering species of Russian thistle associated with TOC and tilling are not responding to chemical factors, and they should increase if disturbance and TOC are the factors most shaping the amended communities. On the other hand, red threeawn should increase if chemical changes in pH or pCu are most strongly affecting the communities.

Russian thistle increased dramatically and dominated the herbaceous vegetation in the fall in the East and North plots immediately after tilling and application of organic matter, which created ideal conditions for this pioneering species capable of rapid invasion; however, it cannot persist long (Biondini et al. 1985). In the East amendment plot, it was quickly replaced by another colonizing forb (golden crownbeard [VEEN]; **Table 15**), and then partly replaced by bristlegrass, a more competitive colonizer that apparently requires more time to respond to the resetting of the community to an earlier successional stage (Roemer and Schultes 2010). Feather fingergrass also is a more competitive colonizer able to invade near the end of the 5 years (**Table 15**). It outcompeted bristlegrass only in the depression within a corner of one of the tilled plots, where the soil is likely more saline (it is a halophyte, USDA Plants database, see **Appendix B-21**). These species likely are responding most to physical changes and access to the nutrients (in manure and decomposing plants), not pH or copper changes (bristlegrass was present in low pCu soils in ERA 3 in 1999; **Appendix B-21**). Red threeawn, which occurs in seral and climax communities, may be responding to the lime increasing pH, because it appears in the East tilled plot in the last year. This may indicate that the plant community in the East plot is beginning to respond to the liming by 2013.

Notably, other grass species (such as the gramas and other threeawns) are most abundant in low pH and pCu areas when West plots are excluded. They are not growing in such soils because of chemical preference (see **Figure 13b**), but because these areas are the least disturbed, represented by the untreated reference areas. These species are late successional species (**Appendix B-3**). Sampling using the CCP protocols in 2013 indicated that sideoats grama had returned by 2013, and may spread over time as the community recovers from the disturbance. It was not observed on the East reference plot in 2013 (**Table 15**) or 2014 (**Appendix B-21**) or in similar rocky habitats (**Appendix B-21**) after the white rain, which indicates that this species may be responding to decompaction of the soil rather than chemical changes. Overall, in the first 5 years, the species establishing on the East amendment plot indicate that tilling and TOC appear to be mostly shaping the community composition more than the pH change.

In the North amendment plot, after Russian thistle died back, it was replaced by silverleaf nightshade [*Solanum elaeagnifolium*; SOEL], the non-native lambsquarters [*Chenopodium album*; CHAL], and carelessweed [AMPA]. Silverleaf nightshade and carelessweed fall along the pH/pCu vector in the positive direction and may be responding to both the tilling disturbance and the increase in pH and pCu (**Figure 13b**). Both species increased on the North reference plot after the white rain (**Table 15, Appendix B-14**), which may support that these species are responding to soil chemistry changes, though it is unclear if the additional lime beyond the white rain contributed to the change. Sideoats grama is sporadically present before (March 2008 tissue sampled in **Table 8**) and after the white rain on the amendment and reference plots (**Table 15, Appendix B-14**; present some years, not others), making it difficult to evaluate if it is responding to pCu improvements from the white rain or amendments. The results suggest that the community may be responding to pCu changes, but the weeds responding to the change are outcompeting the more desirable grasses.

The Northeast plot experienced no change in pH or plant uptake of copper; therefore, changes in the community are likely only due to disturbance from being sprayed or crushed during amendment application. The rapid forb pioneers of bare soil did not establish because the disturbance did not remove all plants. Instead, shrub cover increased. More details on plant community changes progressing with succession are provided in **Appendices B-21** and **B-3**.

Precipitation for the 3 months prior to sampling was added to the CCA on **Figure 13c** and did not change the biplots much or influence conclusions. Precipitation was highly correlated and more significant than TOC (see **Appendix B-22**), which probably indicates that the pioneer species taking advantage of conditions created by higher TOC also are abundant when precipitation is high. For example, the annual forb, carelessweed (*Amaranthus palmeri*; AMPA) was common during the wet year in 2013.

The finding that higher pH (if it occurred) had a weaker positive effect (on the East plot), no effect (on the Northeast plot), or negative effect (more weeds than rangeland grasses on the North plot) compared to the TOC and tilling variables in the mesquite/grama community suggests that the remedial actions are not always creating the intended community changes within a 5-year time frame. Rather, they have increased ruderal, annual species. The most aggressive annual species dominating the plots in 2013 (carelessweed and golden crownbeard are associated with tilling (blue labels on **Figure 13b**). These species can be toxic to livestock if consumed in large quantities, and thus are not improving rangeland condition (see **Appendix B-3** discussion). Golden crownbeard also entangles nesting birds (HNIS 2005), though birds were observed feeding on its seeds, so it has some wildlife value. Carelessweed is relished by livestock but is poisonous when nitrates are higher in the soil, and thus this change from the amendments is also not beneficial (TAES 2011, AgriLife Extension 2014). Nitrates were elevated by the addition of organic matter, especially in the North and East plots (**Appendix C-11**), which puts cattle at risk**.** Carelessweed also has low value to wildlife according to the U.S. Department of Agriculture (USDA) plants database (USDA 2014).

Fortunately, these two species appeared to be on the decline when plots were observed and photographed (see **Appendix D**) after this study was completed in fall 2014. Eight years later in 2016, only the North amendment plot still supported a large amount of carelessweed (see photolog in **Appendix D**). The East amendment plot still had a large amount of golden crownbeard. These species were either a minor component or non-existent in fall 2014 on the haul roads that were “tilled” in 2003 (see **Appendix D**). The reasons for differences are discussed in **Appendix B-21**.

Because of concern about toxic species and loss of grasses, the section below discusses how treatments changed the quality of the habitat for wildlife and livestock.

5.3.3.3 Amendment Plot Changes in Grasses, Annual Species, and Species Composition

When evaluated by each location, not all plots lost grass cover at the end of the 5 years from the disturbance of the treatments. The East amendment plot increased its rangeland grasses over time, whereas the North and Northeast amendment plots reduced their rangeland grasses (see **Figure 10**). Because rangeland grasses are important to livestock, trends in rangeland grasses, as well as changes in species composition favorable or detrimental to wildlife or livestock resulting from each remedial technology, are discussed below in more detail by plot location. First, the effect of the white rain on species present is discussed to separate changes due to white rain versus the treatments. Then the effect of the treatments, whether from physical or chemical changes, is evaluated.

The fact that the plots were treated with combinations of tilling, liming, and organic matter added introduces uncertainty in the analyses as to which technology is increasing each species. **Appendix B-21** attempts to separate effects of the different remedies to assist in FS decisions using information from other studies. That information also is used in the following assessment.

East Plot White Rain Effect. The species that increased or appeared after the white rain on untreated plots may represent species that were adversely affected by low pH and pCu. However, reference plot species composition may be influenced by the adjacent disturbed plot invaders spilling over into reference plots (see **Appendix B-22**). **Appendix B-21** discusses species that increased after the white rain in areas without adjacent recently disturbed plots (ERA 2 and ERA 3). Species that appeared on the East reference plot and these ERA plots after the white rain that were missing before and might not be a spillover from the tilled plot include beardgrass (*Bothriochloa barbinodis*), silverleaf nightshade, and carelessweed (**Table 15, Appendix B-21**). An increase in these species on amendment plots may indicate a positive response to pCu changes.

East Plot Treatment Effect. The shift in community composition in the East amendment plot from amendment/tilling shown by the CCA appears to be from a large increase in both non-woody, annual and grass life forms (**Figures 10** and **11**). In contrast, the East reference plot had comparably few grasses and annuals (see **Figures 8** and **10**). After the multiple treatments (white rain, tilling, and organic/lime amendments), the grasses on the East amendment plot had increased to 39 percent of vegetative cover in 2013 compared to trace amounts on the pre-amendment and reference plot; forbs changed less, increasing to 58 percent compared to 54 percent on the reference plot (see **Figure 10**). Most of this herbaceous increase, however, was from an increase in dominant annuals (golden crownbeard, carelessweed, feather fingergrass, and possibly bristlegrass, if it was an annual) rather than from an increase in perennial grasses (**Figure 8**).

The tilling disturbance and increase in nutrients (associated with higher TOC) on the East amendment plot apparently favored some annual species that dominated the community, particularly golden crownbeard (which turns the plot yellow with its flowers in the fall), whereas it is not noticeable in the adjacent reference plot. Golden crownbeard may have been introduced via seeds present in the organic matter (City of Ontario 2013), especially because it has a synonymous common name of "cowpen daisy," and because manure for this pilot project came from cow pens. Also, golden crownbeard was not common on the ripped haul roads and other disturbed areas that did not have manure applied. However, it has been recorded in areas in the STSIU in 1997 (in rangeland polygon with the North plots; **Appendix A**). After this study was completed, a field inspection of the East amendment plot in 2014 (6 years after treatment) identified the first evidence of a reduction in golden crownbeard, which was being replaced by more bristlegrass growing on the plot (see photo in **Appendix D**).

As illustrated by the CCA, the increase in disturbance from tilling on the East amendment plot did not favor most of the grass species (see **Figure 13b**), except bristlegrass and feather fingergrass. These two species account for the large increase in grasses on the East plot. As discussed in the previous section, the CCA results indicate that these grasses are responding to the tilling disturbance rather than to pCu changes. The CCA shows that late-successional grasses of the desert plains, particularly three grama species and the more subclimax species Arizona threeawn (*Aristida arizonica*; Clements 1916), are reduced by the severe disturbance from tilling. In contrast, the two early seral species of bristlegrass and feather fingergrass (Humphrey et al. 1932, Roemer and Schultes 2010) were able to establish after tilling (when weedy, annual forbs were on the decline). Red threeawn, which can be an early stage or climax species, also established. These grasses of this early seral stage were gaining in cover toward the end of the 5-year period; therefore, the late-successional stage species are likely to require much more than 5 years to recover.

Tilling appears to be the main driver of grass cover and composition changes because Russian thistle invasion after tilling followed by other weedy annuals and early successional grass species is typical of what has been observed in unexposed study areas (Gelt 1993, Biondini et al. 1985, Romme et al. 2003; also see succession section in **Appendix B-3**). Although conclusions are uncertain because of many correlative factors that occur in the field, the results tentatively suggest that equipment and lime/manure disturbance or tilling causes a reduction in grass cover that does not recover in 5 years (see **Appendix B-21**).

The lack of grasses on the East plot before treatment is most likely a relic of past or current overgrazing (or past pCu impacts) that compacted or removed topsoil, which is why it is in poor rangeland condition. The tilling converted the compacted rocky soil to a more granular, favorable medium for growth, which increased total cover and grass cover. After tilling, this amendment plot was greatly improved and classified in fair/good rangeland condition in 2014 as shown by a change in the OAT score from 13 to 39, the latter assigned to it during the field work for the phytotoxicity and community study (STS-PT-2013-17; Arcadis 2017b). Such a large change in rangeland condition probably impacted the community composition more than the small change in pH that occurred with the liming, especially because the white rain already increased pCu without changing the rangeland condition, yet was ineffective at increasing grass or total cover on the East reference plot. Logically, the increase in cover and grasses was from the tilling, and this conclusion is further supported in **Appendix B-21**.

<u>North Plot White Rain Effect.</u> The white rain appeared to increase silverleaf nightshade and carelessweed on the North reference plot (**Table 15**). Vegetation community data are unavailable for other fair rangeland plots on relatively flat ground subject to the white rain to confirm this finding.

<u>North Plot Treatment Effect.</u> Unlike the reference plot, the plant community on the North amendment plot did not improve once accounting for the white rain plus treatments. The North amendment plot was subjected to mostly the same treatment as the East amendment plot (except lower rate of organic matter applied), but it responded differently, probably because it is in fair rangeland condition. The North amendment plot showed an increase in non-woody vegetation after treatment (see **Figure 10**). However, grass percentages, total cover, and diversity measures did not improve (grass cover and evenness actually decreased from treatments) relative to the reference plot, likely because the North plot pre-treatment had more grass cover and species to begin with from being in better rangeland condition (despite its estimated pre-white rain soil pCu of about 2.0). Grass species before the white rain event included the following perennial species: vine mesquite, Arizona threeawn, and to a lesser extent sideoats grama and beardgrass; **Table 15**). Vine mesquite was thriving on the site before treatment (15.5 percent cover) despite tissue copper concentrations in the winter of 105 mg/kg. This species has continued to be supported at similar cover levels post-amendment. Arizona threeawn was present at 10.5 percent cover with 188 mg/kg copper in its tissue before treatment. This species has not returned to the amended plot (and was never in the reference plot) since the disturbance and lime/tilling treatment (see **Table 15**). Similarly, beardgrass has not returned, though it increased in other areas without disturbance that were altered by the white rain (**Appendix B-21**). Unlike the poor rangeland in the East plot, disturbance to fair rangeland sites to enact a chemical remedy may do more harm than good, causing a loss of grasses.

Carelessweed, an annual forb, may be partially responsible for the lowered evenness and loss of grass cover on the North amendment plot, as it characteristically outcompetes other species under the right disturbed conditions. This aggressive species appeared on all plots, but has most heavily invaded the North amendment plot, appearing first in this plot in December 2008 and reaching its highest abundance on all the plots in 2013. This species may be responding to the higher pCu resulting from the white rain event (see **Figure 13b** where it is associated with higher pCu); it was not prevalent on low pCu soils at 1999 ERA locations (Newfields 2005). It became common throughout Chino (even in the seed collection area in Arcadis 2017b) in 2013, but was especially abundant on the tilled North plot. It apparently invaded from nearby areas, taking advantage of the wet conditions of 2013 following 2 years of drought that created intermittent bare patches for invasion. It was present in the STSIU before the white rain, documented as common in the rangeland polygon of the North plots in 1997 (see **Appendix A**).

Carelessweed, though an aggressive annual, does not appear to be as good an initial colonizer of disturbed areas as Russian thistle (*Salsola tragus*) or golden crownbeard, but did well in the last year of the study. In the fall of 2014, after the study was completed, a field inspection identified that carelessweed was greatly reduced on the North amendment plot. However, grasses did not appear to be replacing the carelessweed (see photolog in **Appendix D**). It disappeared from many areas in 2014, yet by 2016, it was still present in moderate amounts in the North amendment plot.

Precipitation and season sampled also probably had little to do with loss of grasses in the North amendment plot based on field observations and the data, though a wet year following drought may have slowed grass recovery. Grasses could not gain much of a foothold initially when Russian thistle dominated. When the thistle died out, other annual weeds, like carelessweed, colonized and limited grass recolonization. The higher precipitation in 2013 following 2 drought years increased weed abundance in 2013, slowing recovery of the grasses, especially late successional grama species.

When precipitation and season were added to the CCA (**Figure 13c**), the following forbs invading after tilling were associated with higher precipitation (species common on the tilled plots): Russian thistle (SATR), golden crownbeard (VEEN), carelessweed (AMPA), bristlegrass, silverleaf nightshade (SOEL), and scarlet globemallow (*Sphaeralcea coccinea*; SPCO; **Figure 13c**). These forbs appear to have outcompeted the perennial or late-successional grass species (e.g., gramas [BOCU, BOGR], Arizona threeawn [ARAR]) that were originally present on the North plot; the grass species may be most competitive with weedy annuals during drier years.

The lack of improvement in grasses on the North amendment plot from treatments when compared to the East amendment plot also may be related to less effective destruction of mesquite. Mesquite re-sprouted quickly on the North amendment plot but not the East plot, covering 20 percent of the North plot within 6 months. This suggests that mesquite root masses (which sprout) survived the tilling on the North plot. Soils are deeper on the North plot than the East plot, which may allow deeper mesquite root masses to survive.

Nevertheless, the most likely reason the vegetation quality in the North amendment plot did not improve from the combined effects of the white rain and amendments, despite its estimated low pCu of about 2.0 in 2006, is because it already had fair rangeland condition with 29 percent of the vegetation cover in grasses and 49 percent of the cover in herbaceous plants (see **Figure 10**) before amendment application and tilling. This plot had less room for vegetation improvement from remediation than the East amendment plot.

Northeast Plot White Rain Effect. Though the white rain lime may have decreased total cover, it appeared to increase silverleaf nightshade, vine mesquite, tobosa, and carelessweed on the Northeast reference plot (**Table 15**). Vegetation community data are unavailable for other fair rangeland on slopes subject to the white rain to confirm this finding.

Northeast Plot Treatment Effect. Relative to the Northeast reference plot, the CCA showed that the Northeast amendment plot community shifted mostly along the time since disturbance gradient. The Northeast amendment plot improved in total cover (**Table 16a**) but lost most of its grasses (**Table 16b**) after the disturbance of spraying/spreading lime and organic matter on the plants (**Figure 10**). Sideoats grama and blue grama (*Bouteloua gracilis*) comprised about 10 to 15 percent of the vegetation cover before amendment and on reference plots (see **Table 15**). Afterward, grasses in 2013 dropped to 2 percent of the vegetative cover on the circular sampling plots (**Figure 10**). Moreover, vine mesquite (a grass) is now more prevalent on the reference plot than on the amended plot. However, grasses may be more prevalent than the circular plot vegetation data indicate because cover of grasses was 6 percent (bristlegrass, vine mesquite, tobosa [*Pleuraphis mutica*]) based on the CCP dataset. Nevertheless, grasses were still low compared to pre-amendment levels. The disturbance from the amendments (despite no tilling) apparently created the opposite effect desired; it reduced perennial rangeland grasses rather than increasing them and set back the community to an earlier successional stage (see **Appendix B-3).**

It is likely that the disturbance, and not other environmental variables such as precipitation, caused the initial reduction in grasses in the amendment plot because of the opposite initial increase in grasses in the reference plot. Both plots were exposed to the same amount of precipitation. The grasses did not recover in the 5-year period, despite normal to good precipitation conditions in the subsequent years before the drought in 2011 and 2012. Notably, non-woody cover (**Figure 17**), not grass cover (**Figure 10**), was correlated with precipitation in the Northeast amendment plot over time. Therefore, the grass reduction over time probably was not from precipitation changes but likely from the disturbance setting the vegetation back to an earlier successional stage. Honey mesquite, false mesquite, and whiteball acacia (*Acacia angustissima*) shrubs increased in cover right after the disturbance, displacing the grama grasses. The disturbance gave the shrub species an edge in the competition.

The number of shrub species before amendment application was eight, which reduced to five species afterward by 2013 (see **Table 15**). The Northeast reference plot also showed a similar decrease in shrub species, however, from three species pre-amendment to two in 2013. Shrubs are common on steeper slopes in the area, where grasses may be less important, and the benefit to the shrubs may be the focus of remediation on the steeper slopes. However, the results do not support improvements in number of shrub species or large improvements in shrub cover.

Like the North amendment plot, applying amendments to the Northeast amendment plot, which was in fair rangeland condition pre-treatment, may have done more harm than good for its rangeland grasses because the increased disturbance facilitated increased dominance by the annual species carelessweed. This weed increased as it spread to adjacent reference plots of the Northeast plot and other reference plots (see **Appendix B-3**). This trend reversed, as carelessweed declined greatly in the Northeast plots in fall 2014 after the study was completed and was not evident when photographed in 2016. The Northeast amendment plot likely will recover its perennial grasses more quickly than the other plots, as seen by significant improvement relative to the reference plot on **Figure 11**. The lime and organic matter likely were not the cause of improving total cover (white rain did not improve cover, see **Appendix B-21** on why organic matter is not a good candidate). Because the results do not demonstrate that soil pCu or copper uptake was reduced from amendments on this plot, the observed community changes were likely due to disturbance or other non-chemical factors, which degraded rather than improved the wildlife habitat and rangeland condition of the community (see **Appendix B-3**).

Summary of Changes in Grasses and Species Composition for all Plots.

These findings for all three amended plots suggest that remediating to increase pCu with the combination of the three technologies evaluated in this pilot study may change the community substantially and sometimes in a negative way. The resultant increase in potentially toxic annuals is not beneficial, reducing rangeland grasses or species of high importance to wildlife and livestock in the fair rangeland areas. More benefits are observed in the poor rangeland areas, which improve in rangeland grasses. However, it is not clear if the improvement was from increased pCu, given that pCu did not significantly change in any treated plot. Also, the species that increased were species that respond to heavy disturbance from tilling. Most likely, the improvement was from tilling, improving the soil representing poor rangeland condition, which converted the area to good rangeland condition.

The loss of good quality habitat on the North amendment plot and the finding that liming and organic matter reduced grasses on the Northeast plot, in combination with the finding of no concrete evidence that the treatments were effective in remediating chemical impacts, suggests caution in applying treatments in situations that may cause more harm than good. Possibly, the low pCu reduced vegetation cover in areas around the smelter or tailings many years ago resulted in eroded, rocky soils in poor rangeland condition. In that case, tilling could help remediate that resultant physical impact. However, that is uncertain because many areas in the STSIU were overgrazed and no method exists to identify which areas, if any, were physically degraded by historic mining processes verses historic grazing. Given this uncertainty, the benefits and costs of remediating should be carefully weighed.

Possibly, in the long term, after 15 to 20 years or more (see Section 5 in **Appendix B-3**), the perennial species will return to fully dominate in areas remediated to increase pCu, but the pilot study to date does not provide helpful information to support that the resultant community will eventually improve in wildlife habitat or rangeland quality except on poor rangeland sites. Periodic, long-term monitoring of the plots could provide more information on recovery of the fair rangeland communities, and will reveal whether the rangeland grasses will increase in cover compared to their cover before amendment. However, the literature indicates uncertainty of recovery, even in 50 or 100 years. This high uncertainty indicates that it is best not to remediate fair rangeland, where long-term damage is highly likely with very slow recovery. Seeding desired species may accelerate the return of perennials on more level ground that was tilled, but it is uncertain whether it would be effective in already vegetated untilled locations on steeper slopes.

Tilling of the haul road successfully established abundant grasses without seeding. Haul roads on relatively level, poor rangeland areas with low pCu that were ripped 12 to 18 inches deep in 2003 without seeding or amendments have had desirable rangeland grasses growing in the furrows for a number of years. Specifically, the poor rangeland site ERA 2 documented in Newfields 2005 has a ripped haul road adjacent to it that has abundant grasses growing in the furrows that established before the white rain. This location had a measured and calculated pCu of 3.87 and 4.1 in 1999, respectively, and of 6.9 (calculated) in 2013 (Arcadis 2017b) post-white rain. The adjacent unripped area supports primarily mesquite (see photo in **Appendix D**). The haul road grasses became abundant several years after their ripping, replacing weedy annuals that initially arrived (such as Russian thistle). This pattern is similar to the successional trajectory observed in the East amendment plot after tilling (see community composition descriptions in **Appendix B-3**), except the East amendment plot became dominated by annual weeds. This haul road example indicates that tilling alone may help improve vegetation communities on poor rangeland areas that already benefitted from the white rain (pH increased to more than 5). If the white rain did not increase pH enough, tilling plus lime may be needed on these rocky, eroded areas. It is uncertain if remediation for copper is needed on some poor rangelands, however, because the poor quality of the communities may be due to overgrazing and the resultant loss of surface soil rather than to copper toxicity. If copper phytotoxicity is demonstrated for an area, such remediation may be beneficial. Toxicity could be demonstrated using results from the phytotoxicity and community study (Arcadis 2017b) on site soils and with an evaluation of plant signs of copper distress at specific locations (e.g., chlorotic or many dead leaves or branches on shrubs). Notably, an improvement in soil chemistry (pCu) from the white rain event and natural attenuation does not necessarily mean that grasses or cover will increase if rangeland condition is poor. The East reference plot, despite its improvement in chemistry, still has low cover of grasses. Remediation of poor rangeland using lime and/or organic matter without tilling may not be successful because it will still be rocky, compacted soil.

More discussion on integrating the phytotoxicity and community study results with the weight of evidence from this study and other studies (see **Appendix B-21**) is provided in Section 8 to assist in using this information in the FS.

6. Weight of Evidence from Primary Metrics

The results for soil of the treatments for this amendment study support that pH may have increased from tilling when combined with lime and organic matter amendments, even though the plots exhibited high pH greater than 5.5. The effect on pCu from this combination is uncertain due to high variability in copper and low power in the tests, but the results suggest that the pH increase observed in the tilled plots has persisted. The slight decrease in copper in the plant tissue from lime amendments (possibly only by 1 mg/kg) to non-toxic and near background levels of 13 mg/kg in herbaceous plants suggests that the insignificant change in pCu may have had a small effect on copper uptake. The white rain already accomplished most of the potential increase in pCu and decrease in copper uptake. Because the reference plots also increased in pCu (e.g., East reference plot) or exhibited pCu after 5 years (North and Northeast reference plots, **Figure 4b**) similar to the amended plots (possibly because lime took time to infiltrate below a few inches), the chemical benefit of amending or tilling after the white rain already limed the plot may be minimal to non-existent. This conclusion is uncertain because the increases in the reference plot (East) may be just a natural long-term fluctuation in pCu, and the amendment study period is too short to determine this.

The response of the primary metrics (pCu, copper in plant tissue, species richness, percent cover, and the species composition that established) to each management action (tilling, liming, organic matter, and white rain/natural attenuation) for each plot type is indicated in **Table 17**. The effectiveness of each management action was evaluated initially and after 5 years by determining: (1) if the response was an improvement from reduction of copper bioavailability; (2) if so, did it meet target criteria (for metrics with such criteria); and (3) if the response was an improvement greater than that observed on the adjacent reference plot (if reference plot data were available). The appropriateness of the management action for the plot type with its pCu was then assessed and a recommendation made for that plot. The plot types represented included:

- Relatively flat slope in poor rangeland condition with pH over time averaging about 5.7 (with range over time of ± 2.4) and pCu averaging about 4.6 (with range over time of 2.1)[29], as represented by the East location

- Relatively flat slope in fair rangeland condition with pH averaging 6 to 6.6 (range over time of 0.9) and pCu averaging 4.3 (range over time of 1.9), as represented by the North location

- Steep slope that cannot be tilled that is in fair rangeland condition with pH averaging 5.7 to 5.9 (range over time of 1.2) and pCu averaging 3.5 (range over time of 2.5) as represented by the Northeast location.

Because plots with lower pH and pCu were not treated, these recommendations do not necessarily apply to plots that are more impacted. However, **Appendix B-21** assesses other information available for the STSIU combined with this study to assist in separating effects of the three remedial treatments in different scenarios for different soil conditions to ultimately inform FS decisions. This assessment is summarized in Section 8 and **Table 18**.

After weighing the evidence presented in **Table 17**, the Amendment Study shows that the white rain event and subsequent natural attenuation were effective at improving all of the metrics except plant cover. However, pCu change from the white rain did not reach the pre-FS RAC level for the poor rangeland (East) and steeper slope (Northeast) areas[30].

Tilling, combined with lime and the white rain, at relatively flat locations was effective at increasing pCu to above the pre-FS RAC levels and decreasing copper uptake in herbaceous plants. It is unknown if the treatments added more to the uptake reduction than white rain, and if so, likely the contribution was very small. The benefit of this change in pCu to the plant community in terms of richness and cover was only observed on the poor rangeland location (East). However, that benefit to cover likely was from

---

[29] Average is before treatment but after white rain and range estimated from reference plot range over time in **Table 4**.

[30] Probably because white rain did not deliver enough lime on flat slope and also runoff losses on steep plot.

decompacting the soil after tilling (see **Appendix B-21**), given the low confidence that the soil pCu changed from either lime additions or mixing the copper in the soil more evenly to 8 inches. The high confidence result is that the white rain increased pCu. Comparison to the reference plots receiving white rain liming shows that vegetation cover changes in the poor rangeland are from decompacting the soil, not from the white rain lime. The benefit was not observed in the fair rangeland North amendment plot, which already had decompacted soil and relatively good grass cover and richness. Its plant community did not improve relative to its adjacent reference plot because of the disturbance from tilling and conditions favorable to weed invasion from both the organic matter and disturbance. Statistical comparisons of tilled to untilled plots suggested that tilling alone to an 8-inch depth was not effective at significantly reducing total copper concentrations in the soil (and hence, probably pCu).

The amendment study did not evaluate a treatment of only tilling, but haul roads in low pCu areas in poor rangeland condition (compacted with soil erosion) were ripped without any other treatment and provide an approximate example of “tilling” only. However, ripping was deeper than 8 inches, with the haul roads ripped to 12 to 18 inch depths. The successful haul road results of an abundant growth of grasses suggest that deeper tilling without other amendments than the white rain may be effective at creating granular soils indicative of good rangeland condition, thus improving wildlife habitat and conditions for livestock. It is unknown if copper concentrations were concurrently reduced by mixing high concentration surface soils with subsurface soils during the decompaction, and if the response was mainly from the physical changes or was a result of both chemical and physical changes. Most likely it was both (see discussion of tilling effects in **Appendix B-21**).

Spraying lime without tilling was only evaluated on the steeper slope location (Northeast) and was not effective at increasing pCu or plant uptake of copper. However, when lime was applied with tilling on the two relatively level plots, the combination was effective at increasing pH, but not necessarily pCu. Effectiveness of spraying lime alone on relatively flat areas is unknown because this combination was not evaluated in this pilot study. However, the white rain deposited “lime” and indicated high effectiveness of lime alone in increasing pH and pCu on relatively level areas, with more limited effectiveness on steeper areas.

Though species richness increased, the large change in soil pCu from the white rain lime (increased by more than 1 unit) did not result in a change in total vegetative cover amounts on the relatively flat North and East areas that would benefit wildlife or livestock, whether in poor or fair rangeland condition (see **Appendix C-21** for discussion of white rain effects alone). Therefore, benefits of adding lime alone to the plant community seem limited, especially if pH is high (above 5.5). The white rain report (Arcadis 2017a) showed that pH increases from liming were generally restricted to plots with pH < 5.5.

Organic matter may not have been effective as measured by the primary metrics (pCu did not significantly increase, nor copper uptake reduce) and possibly was detrimental to the plant community. Statistical power was poor to detect a change in pCu, creating uncertainty about its effects. Based on a literature review, organic matter applications in semi-arid to arid areas often lead to decrease in species richness, invasion by weedy annual species, and very little improvement in the vegetation community (see **Appendix B-21**). Also, the haul road tilling produced a community with fewer annual species invading, possibly because organic matter was not applied.

A thorough or quantitative evaluation of copper phytotoxicity was not conducted as part of this study; however, copper phytotoxicity in individual plants, as indicated by visible tissue necrosis, chlorotic leaves, dead stems, or browning that was different in amount or timing from natural senescence, was not observed during surveys in either the treated or reference plots. The health of the communities of the reference and treated plot appeared the same. Notably, the signs of phytotoxicity may not have been seen due to the timing of the first vegetation survey, which took place after the natural lime application caused by the white rain.

The effect of the remediation on the plant community and ecosystem as a whole must be evaluated before recommending which remedial actions are appropriate for each plot type. The overall effect of the pilot study remediation was an increase in potentially toxic and aggressive annual species of low value to livestock and wildlife, species that have gained a foothold in response to the disturbance and possibly the increase in organic matter, or from being introduced in the manure. The increase was large and of most concern in the tilled plots. In particular, carelessweed became dominant, and this species accumulates nitrates to high concentrations in its tissue from soils with high nitrogen content. Soils in this study had elevated nitrogen from organic matter applications, which puts cattle at risk to this toxic species. The nitrates can accumulate to levels that can poison and kill livestock.

Chino is concerned about the ramifications of recommending remedial actions that may result in death of livestock. Golden crownbeard, which may have been introduced in the manure or just invaded after tilling, also is dominating and carries toxins of concern to livestock. These aggressive species may be reduced over time, as seen during later visits in 2014 and 2016, allowing more perennial grasses to establish, but carelessweed is still abundant in the North plot. In fair rangeland areas, the successional process after a major disturbance can take many decades to recover its original perennial cover and favorable rangeland grasses (see **Appendix B-3**). Disturbance on a large scale in the STSIU may invite many invasive species as well as aggressive annuals and degrade the quality of the current habitat for a long time.

Rangeland grasses in the area do best in soils with little disturbance and, therefore, areas in fair rangeland condition similar to the North location should not be tilled or damaged by spraying lime and spreading manure, even if pCu is low. The pCu was low (estimated to be around 2) on the North plot in 2006, yet after the white rain in 2008 and even 5 years thereafter, it decreased in cover, while the adjacent reference plot increased in cover[31]. Remediation is ultimately designed to improve plant communities, not to increase pCu (because pCu is being increased only to improve plant communities), and this study supports that the amendments and tilling did not improve the plant communities in fair rangeland condition.

Considering the weight of evidence in **Table 17**, the best approach in areas where the pCu has been steadily increasing after the white rain event (such as North and East locations and locations identified in the white rain report, Arcadis 2017a) is to allow that trend to continue and to monitor natural attenuation and assess if it reaches the pre-FS RAC criteria. For relatively level areas showing no trend in improvement in pCu, and where the rangeland condition is poor, the site could be considered for liming and tilling to increase pCu if low pCu is the cause of its condition. Tilling is recommended before trying the combination of liming and tilling given the high success rate of the tilled haul road. Addition of organic matter is not recommended. Seeding with desirable species may be a better choice than applying organic matter because organic matter increased soluble copper and was not needed to establish grasses in low pCu, poor rangeland soils that were ripped to reclaim haul roads. However, seeding is not necessary because seeding was not necessary to establish desirable grasses on the haul roads.

For steeper slopes that cannot be tilled due to safety or equipment-related constraints in rough terrain with boulders, the remedial options are limited, and none evaluated for this study are beneficial. The results of this study supported no significant change in pCu or reduction in copper uptake on the steeper slopes with any of the three remedial

---

[31] Cover (but not richness) was still higher in 2013 in the North amendment plot than its adjacent reference plot, but this was also the case before the white rain.

technologies. Application of lime and organic matter mainly disturbed the plots, increased soluble copper, and decreased rangeland grasses, appearing to do more harm than good.

These conclusions, based on the weight of evidence, only apply to the remedial techniques assessed in this study. Much uncertainty is associated with these conclusions because this investigation was designed to be a simple, initial pilot study, not a research study. Treatment combinations were not replicated, and each location exhibited unique conditions that confound interpretation of the treatments on pCu and limit generalization of results to the same type of areas. The conclusions may not be easily extrapolated to the full diversity of types of areas found on the STSIU (e.g., bedrock areas, poor rangeland with granular soils). Uncertainties associated with this amendment study are discussed in Section 7. After reviewing information beyond this study, a summary of recommendations for each remedial technology based on evaluating each separately is also presented in Section 8.

7. Uncertainty

This study was designed as an exploratory pilot study intended to evaluate the effect of amendments on copper, assuming that a large effect would occur that would be detectable with a simple design with four plots. As it was not a research study, it is difficult to interpret the results with complete certainty. However, using quantitative tools and qualitative concepts and graphs that analyze data in different ways, support for the conclusions may be enhanced and the degree of uncertainty reduced. A drawback of the study design is that the 2 years of monitoring data before treatment had to be reduced to one sampling period after the white rain.

The white rain weakened the ability of tests to detect differences, but at the same time provided a valuable natural experiment of the effect of lime on the soil and vegetation communities across the STSIU. This section discusses uncertainty associated with conclusions that depend on: (1) shifted locations of some study plots just before treatment, (2) adequate power to detect differences, (3) limited reference data and substitutions of less collocated data, (4) ERA plots, (5) assumptions of persistence of effects, (6) accuracy of dormancy bias adjustments, (7) assumed long-term recovery, and (8) no climatic interactions biasing results.

7.1 Moved Plots

As discussed in Section 2.1, the North and Northeast amendment and reference plots were moved from their original 2006 locations in July 2008 and May 2008, respectively. Although the new locations were nearby (**Figure 2**) and chosen so that pre-amendment site conditions were as consistent as possible with the original locations, underlying differences exist. For example, the Northeast plots were both moved to a less steep location, the North reference plot was moved to a less rocky and erosive location, and the North amendment plot was moved to a less erosive location. Baseline vegetation condition was sampled before plots were moved, and the baseline soil condition was sampled in the North plot before the plot was moved (whereas baseline soil but not vegetation was sampled after being moved for the Northeast plot). It is uncertain how representative the moved plots are of the original locations for the vegetation for both locations and for soil at the North location. If they are very different, the results may partly reflect these differences, not differences from treatments.

7.2 Statistical Power

The inherent variability in sampled soil constituents and sampling error introduce uncertainty in conclusions. If the statistical power of the analyses is too low to detect a significant and biologically important difference resulting from treatments, the results and study conclusions become more uncertain. The lack of power to detect significant differences can occur when sample sizes are insufficient or when soil constituents are highly variable. Power results are presented in detail below for the various statistical comparisons in this report that were statistically insignificant to identify which results may pose highest uncertainty.

7.2.1 Comparison of Amendment and Reference Plots (Table 11)

A sample size analysis was conducted in 2012 to evaluate if differences in soil pH and pCu likely could be detected between amendment and reference plots in a paired t-test with sufficient power. This paired t–test evaluates changes in space, not time (same years compared but one is a treated and one a reference plot). Such an analysis requires specifying the standard deviation[32] obtained from statistical tests applied to past data. It

---

[32] For ANOVAs, the standard deviation is the square root of mean square error in the ANOVA table.

also requires specifying the sample size planned, desired confidence, and desired target effect size (e.g., change in pH in units or percent change in copper) considered biologically meaningful. A power analysis in 2012 (Arcadis 2013) indicated that sample size needed to be increased from three to eight per plot. Switching to eight samples was estimated to provide:

- 87% power to detect a difference of 1 s.u. in pH with 95% confidence, using a standard deviation of 0.79

- 70% power to detect a 1.5 unit pCu difference with 90% confidence, using a standard deviation of 1.75 units

When only three samples were collected, the data provided

- 25% power to detect a difference of 1 s.u. in pH with 95% confidence, using a standard deviation of 0.79

- 27% power to detect a 1.5 unit pCu difference with 90% confidence, using a standard deviation of 1.75 units

However, rather than comparing pairs of plots for each location individually, the final statistical test used in **Table 11** to detect differences from treatment was a two-way ANOVA for each of the four locations with time and treatment as factors in each of the 26 comparison (4 plots x 6 soil analytes each plot). This latter approach increases the power of the test so that smaller differences (effect size) between the pairs of plots can be detected with statistical significance. Both pH and pCu were significantly higher on amendment plots than reference plots at $P < 0.05$ for all except the North location, which exhibited a significant difference at $P < 0.10$ (**Table 11**). Therefore, with the increase in sample size in the latter 2 years, power was adequate to detect differences at the 90 or 95% confidence level between the amendment and reference plots in two main metrics (pH and pCu), even though sample size was not the same in every cell of this two-way ANOVA. The numbers of samples were equal or close to equal for each treatment within each time period, however, and this increased robustness of the unbalanced ANOVA. Unbalanced data are expected in environmental monitoring programs and often still give acceptable results (Smokorowski and Randall 2017), particularly if every year is sampled.

Below is a power analysis in SAS (GLMpower procedure) for comparisons in **Table 11** that were not significant. Tests in that table that produced statistically significant results at P < 0.05 or near significant results (P<0.10) are not addressed because they had enough power to identify differences with confidence of 90 to 95%. For all the soil constituents tested, power was adequate to detect significant differences between means of a 20% difference or more, as shown in P values in **Table 11** (all significant) except for copper in the North and Northeast plot locations and soluble copper in the North plots, as discussed below.

<u>Copper</u>. Ideally, power should be at least 80%, though lower levels of 60 to 80% indicate that a significant difference still might be detected for the majority (at least 60 to 80%) of the time. If the effect size for copper concentrations between treatment and reference areas is targeted to be a 20% difference (and a maximum 20% difference through time) with 95% confidence, then the power is 60% probability of detecting a difference in copper for the Northeast plot (standard deviation of 880 mg/kg) and 33% probability for the North plot (standard deviation of 466 mg/kg) based on results from the SAS procedure GLMpower. This low power of the tests for these two plots as a result of high variability in copper concentrations is creating uncertainty in the conclusion of no difference from reference for copper in these two plots (but see Section 7.3.3 for more complete assessment of uncertainty in copper results below).

<u>Soluble Copper</u>. The soluble copper for the North plot has even lower power than copper because of low total sample size (n = 29 vs. 82 for other constituents). The low sample size was a result of removing all 2011 and 2012 soluble copper results from the analyses because they inadvertently were analyzed at a 20:1 SPLP dilution ratio, not 5:1. The ANOVA for soluble copper had less than a 20% percent probability of detecting a 20% difference from the treatment (with 1.62 log units SPLP standard deviation). Nonetheless, a significant difference in SPLP was detected in the East and Northeast plots because the difference in soluble copper between the two plots was much greater than 20%. However, uncertainty is high around the conclusion that soluble copper did not differ from reference for the North plots.

7.2.2 Differences over Time and Space: BACI Results (Tables 9a and 9b)

The results in **Tables 9a** and **9b** using BACI analysis focus on effects of treatments over time in addition to post-treatment differences in space between the adjacent paired plots. The significance of the interaction term is key to determining treatment effects. As will be discussed below, the results in **Table 9a** and **9b** show trends of weaker power for copper, soluble copper, and pCu in the BACI. The soil pH, however, had adequate power.

Copper. For copper tests in **Table 9a**, the power was not very high for the targeted effect size scenario. If the amendment and reference plot have similar means (within 3%) before treatment, and the targeted difference is to detect an increase by at least 20% after treatment, then the power to detect the interaction term is only about 15%. The power is also only 25 to 30% to detect significant main effects of treatment between plots (space) and periods (time) (using standard deviation of 651 mg/kg for liming, 646 for tilling from these tests).

pH and pCu. For pH and pCu tests in **Table 9a** (with 0.65 standard deviation for pH and 0.95 for pCu from these tests), the power is adequate for pH for the scenario tested but is more limited for pCu. If pH and pCu means are similar between reference and treatment plots before amendment or tilling application (within 0.05 s.u), and it is desired to detect an increase by 0.5 s.u. post-treatment for pH and by 1 unit for pCu, the power to detect the interaction term is 94% for pH (and main effects are 82 to 94%) and 45% for pCu (and main effects are 50%).The higher power for pH is because pH has less variability and was more intensively sampled than copper in May 2008 (pH had 10 to 12 samples per plot before treatment compared to 2 samples per plot for copper). The pCu power of 45% falls between pH (94%) and copper (15%) as expected because it is calculated from both, and the high copper variability reduces its power.

These power analyses indicate that it is unknown and uncertain if the insignificant interaction term showing no benefit of the treatment for copper or pCu was because of treatment ineffectiveness or because of weaker power of the test. For pH, the tests had high power, and therefore the one significant interaction term in **Table 9b** (effectiveness of tilling), provides some confidence (but only 90%) that tilling the lime into the soil increased pH. It must be remembered that the focus of the treatments was on increasing pH, not reducing copper, and to that end, the tests (and white rain report, Arcadis 2017a) support that adding lime when tilled into the soil seems to be effective at changing pH, which should boost pCu upwards. Because of the small effect on pH and high variability in copper, the calculated pCu change from treatments was not detectable with the available sample size and power but logically could have improved a small amount if pH improved and copper did not change.

Soil pH uncertainty. Although the BACI tests had high power to detect small differences in pH, it is difficult to interpret small changes in pH with certainty because of limited confidence, lack of replication in the study design, variability in pH over time, moving the North plot just before treatment, and uncertainty as to the depth of soil that was neutralized. The conclusions of improved pH in tilled plots is based on 90%, not 95% confidence. More importantly, the study design did not include replication of the same treatment in the same topography and rangeland conditions (n = 1 for each combination of conditions). If the same results had been observed in a second set of plots with steep versus level and fair versus poor rangeland condition, the results could be more conclusive and the interpretation less speculative. Soil pH is variable from year to year depending on the randomly chosen sample locations, making conclusions about pH more difficult.

For example, this study shows that the East reference plot achieved a final pH of about 6 in 2013, while the white rain report (Arcadis 2017a) shows that the East reference plot then decreased to lower pH in 2014 (down to 4.9), illustrating that conclusions based on a short time frame of 5 years are uncertain. The North plot was moved just before treatment (and not sampled in new location), which requires assuming that soil conditions did not change from the move, an uncertain assumption. Finally, because pH was not measured in different strata within the 0- to 6-inch zone, it is unknown exactly how deep lime penetrated the soil in the amendment plots over the 5 years. Findings reported in the literature support that migration of the lime initially may not reach a 6-inch depth where many roots grow. In arid, sandy soils impacted by copper mine leachpads in Australia, Golos (2016) tilled soil to 30 cm after liming and found that the lime did not neutralize soil below 4 inches. Possibly, the lime will be more effective over time, but this is unknown. For these various reasons, it is uncertain if the improvement in pH from the treatments beyond the white rain effect is a real trend.

7.2.3 Early Year Differences over Time from Amendments for TOC and C:N (Table 10)

TOC and C:N did not have data available for a BACI analysis and were analyzed through time before and after treatment without reference data for comparison. Using just one sampling period (0.5 year) post-treatment for TOC and C:N, the power of the ANOVA was limited to 50% to detect a target of a half percent difference in TOC and of detecting a C:N ratio difference of 5 after a half year (using standard deviation of 0.442 for TOC and 4.45 for C:N). However, when increased to two sampling periods to evaluate effects after 1.5 years, the power was sufficient to detect significant differences (**Table 10**). Thus, these data were adequate to identify trends in these soil constituents in the early years following treatment if evaluated at least 1.5 years after treatment.

7.3 Limited Reference Data

The pilot study design of the Work Plan was not originally focused on understanding regional variability of plant communities, copper, pCu, or nutrients, including the variability created by the unanticipated white rain event. It is difficult to determine if changes are due to treatment or due to effects unrelated to treatment caused by climate, operational changes, vegetation succession, or the white rain. Longer-term datasets in reference (untreated) areas would be required to assess the variability in the measured parameters in this study and if treatment effects fall within that variability, but are unavailable. The study attempts to overcome this uncertainty by including reference data where available or evaluating other datasets and information available for the region or Site, but ultimately, the study results and conclusions carry a substantial amount of uncertainty as discussed below.

7.3.1 White Rain Effects on pH, pCu, and soluble copper

The white rain analyses have the limitation of having no reference areas unaffected by the white rain. Changes are ascribed to the white rain that could be from other factors including operational changes over the years. Also, soluble copper data are not available on amendment plots pre-white rain to evaluate white rain effects. The only soluble copper data available to compare were the ERA data, and uncertainty exists on the comparability of soil chemistry of ERA locations (with 1999 pH < 5.5) with the pre-white rain chemistry in the amendment plots.

7.3.2 Treatment Effects on C:N, TOC, and Soluble Copper

Analysis of treatment effects on C:N, TOC, and soluble copper do not include data from reference areas sampled in the pre-treatment period. Pre-amendment and pre-white rain C:N and TOC were collected on the amendment plots before they were treated (in 2006 and 2008; see **Table 4**) but could not be paired with collocated or less collocated reference plots for a BACI analysis because such data had not been collected elsewhere nearby. Therefore, a BACI that accounts for regional trends and variability could not be performed for these parameters. Instead, two ANOVA tests replaced the BACI. Reference and treated plot means, averaged over the period of 2010 to 2013, were compared (**Table 11**), and the treated plots before and then 0.5 year and 1.5 years after treatment were compared (**Table 10**). More years were not compared because regional trends may interact with treatment trends, which cannot be compared to reference areas to remove the effect.

To evaluate uncertainty in these results, a graphical, more qualitative analysis of the trends was additionally performed by examining trends of all study plots on **Figure 4b**. This examination of **Figure 4b** trends, combined with results of statistical tests in **Tables 10** and **11**, support that, despite fluctuations, the TOC increased and C:N decreased initially and the change persisted, with TOC being higher and C:N lower in the amended plots than in the reference plots. Evaluating all the data three ways helps reduce uncertainty associated with not having a reference area pre-treatment.

Effects of adding lime and organic matter amendments on soluble copper were analyzed similarly without a BACI, and supported that soluble copper significantly increased just after amendments were applied (**Table 10**). However, **Figure 4b** (ignoring data from fall 2011 to spring 2013, which had 20:1 dilution ratio) shows soluble copper fluctuating substantially in all the plots, and the initial increase may be a significant large fluctuation that does not represent any meaningful increase when compared to the high variability over time. **Table 11** shows that soluble copper is significantly higher in the amendment plots than in reference plots after 2010. These results do not foster a consistent interpretation, and therefore, conclusions about lime and organic amendments on soluble copper are not very reliable.

To evaluate the effect of tilling on soluble copper that incorporates variability over time, a BACI was performed using the untilled Northeast plot as a control plot and the North and East amendment plots as the treated (tilled) plots (**Tables 19a** and **19b**), in the same manner as pCu and copper were analyzed for tilling effects in Section 7.3.3 below. Though the Northeast plot is an uncertain control because it has a steep slope, the results show that the high variation in soluble copper, particularly in the Northeast plot, obscures the initial increase in the East and North amendment plots in soluble copper (log transformed) observed on **Figure 4b** (insignificant interaction term of P = 0.47, **Table 19b**). As stated earlier, the soluble copper data are highly variable, tests have low power, and much uncertainty exists around the results.

7.3.3 Alternate Statistical Analyses without Less Collocated Plots

The locations of reference plots in the pre-treatment year were not consistent for BACI analyses of copper and pCu, as discussed in Section 5.2.4, creating some uncertainty. The use of different reference plots in early pre-treatment years (less collocated plots) than in later years (collocated plots) was required because no pre-treatment data for copper or pCu were available. The use of inconsistent reference plots, some of which are less well collocated, creates uncertainty because copper differences may be due to inherent locational differences rather than representing trends in untreated plots over time. Therefore, an alternate statistical analysis was performed for copper and pCu without using the less collocated reference data. The alternate lime and organic amendment analyses were chosen to be the same ANOVA analyses run on soluble copper, TOC, and C:N discussed in Section 7.2.2. No reference data were included, only a comparison of the pre- and post-amendment periods. The tilling alternate analysis selected excludes reference plots, but still includes the amendment plot that was not tilled, which served as the only reference in a more limited BACI. Note that no alternative analyses were needed or conducted on pH because the BACI included the same consistent and collocated reference plots every year.

For the alternate statistical analyses on effects of lime and organic matter, a mixed model ANOVA without reference plots (with plot location and sampling period as random factors) was used. Because the soil copper may have decreased in many areas after 2010[33], later years were first excluded to avoid amendment effectiveness erroneously being attributed to regional trends. In a second analysis, these later years were included when calculating the post-treatment mean to determine if results were the same. In a third step, the results were compared to graphs of trends for each study plot to assist in the interpretation. Finally, the results were compared to the BACI analysis results in Section 5.2.4 (**Tables 9a** and **9b**) to see if conclusions differ and are uncertain or if the various analyses evaluated together as a weight of evidence determination support a reasonable final conclusion.

The mixed model ANOVA without reference plots produced the results discussed by treatment in the following sections.

7.3.3.1 Lime and Organic Matter

To evaluate lime and organic matter amendment effectiveness using an alternative model, a mixed model ANOVA with no comparison to a reference area was the test used. Copper decreased immediately after lime and organic amendments were applied, but the decrease was not statistically significant in the first 0.5 year or 1.5 years ($P > 0.45$, **Table 20**). The difference was almost a significant decrease from 1,956 to 1,466 mg/kg, when averaging across all five post-amendment years ($P = 0.095$). Soil pCu also did not show a significant increase in the first 1.5 years ($P = 0.462$) after amendment application, but an almost significant increase (at 90% confidence) from 4.1 to 5.1 in pCu when averaging across all post-amendment years ($P = 0.095$, **Table 20**). A challenge with only using the first 1.5 years post-treatment is that the sample size is low, reducing power to detect differences given the high variability in copper and pCu. A challenge with using all 5 years is that copper or pCu may be decreasing over time post-amendment

---

[33] See white rain report (Arcadis 2010a) showing reduction in copper after 2010, which was also observed on the North and Northeast amendment plots.

affecting the post-treatment mean of both copper and pCu, and this decrease may be unrelated to the treatment.

Based upon **Figure 4a**, the decrease in copper after treatment, whether measured after 0.5, 1.5, or 5 years, appears to be driven mostly by the North amendment plot, in which copper concentrations continued to significantly decrease over time in the post-treatment period (see minus sign next to legend on **Figure 4a**). This same downward trend was observed in the North reference plot from 2010 to 2013 (**Figure 4a**). The BACI analysis in **Section 5.2** may shed light onto this result. The BACI indicated that the change in copper was not due to treatment because both the amendment and reference plots had a downward trend in mean copper (**Table 9a**), and therefore the interaction term was insignificant (**Table 9b**). Though each analysis has shortcomings, the weight of evidence based on these different analyses with and without reference plots suggests that the addition of lime and organic matter did not change copper concentrations. Thus, despite uncertainty, the conclusion from the BACI alone appears to be reasonable.

The increase in pCu in the 5-year analysis was influenced by pH changes in the later years over time as well as the decrease in copper. However, the conclusion is the same, that the increase in pH and decrease in copper in some reference plots (East and North reference plots, respectively; **Figure 4a**) from 2010 to 2013 likely represents a regional trend unrelated to the treatments. A decline in copper and increase in pCu after 2010 were also reported for the larger STSIU area in the white rain report (Arcadis 2017a), though the high variability in copper makes significant trends over short 5-year periods uncertain. The finding of no significant change from the lime and organic matter treatment in the early post-treatment years supports the conclusion of minimal effect of treatments on pCu, as does the BACI result in **Table 9b**.

The BACI is only reliable if the less collocated reference plots have copper concentrations and variability similar to those of the collocated adjacent reference plots in 2008. Because this is unknown, the above alternative analyses were evaluated in this section. However, the less collocated reference plots might have been similar to the collocated adjacent reference plots because the mean concentration of the less collocated reference plots before the liming treatment was similar to the mean of amendment plots before treatment (approximately 2000 vs. 2200 mg/kg for amendment, **Table 9a**). It is unknown if the collocated reference plots would have exhibited the same general concentrations (2200 mg/kg) during the pre-treatment period in 2008, but it is quite likely because the slightly higher average copper in the less collocated reference plots matches the finding that the pH tended to be slightly lower in the collocated reference plots than in the amendment plots during the pre-treatment period (5.8 vs.

6.0). It matches expectations because soil copper and pH often are negatively correlated in this area due to stack emissions. The standard error of the mean of the less collocated reference plots was also similar to the amendment plots during the pre-treatment period (435 vs. 450 for lime, **Table 9a**). This suggests that the less collocated plots may have been adequate substitutes for the adjacent, more collocated reference plots. However, conducting the alternate analyses as well as the BACI provides the most complete picture of the uncertainty of the results, given the limitations in the study design. The more complete picture supports that lime and organic matter additions probably did little to change copper and pCu.

7.3.3.2 Tilling

For the alternate analysis, the Northeast amendment plot was used as the only untilled reference (control) in a BACI. The BACI was a mixed-model ANOVA that included trends in the tilled plot and untilled control over all 5 years post-treatment. The results showed that copper did not change in a significantly different way in the tilled plots than on the untilled plot; in other words, the interaction term was not significant (**Tables 19a** and **19b**). Both the original BACI analyses in **Table 9a** and **9b** (which included less collocated plots) and the new analysis without adjacent reference plots support the conclusion of no effect of tilling on copper concentrations. The graphs on **Figure 4a** show that copper concentrations are highly variable in the untilled Northeast plot, making it difficult to identify changes in copper in the tilled plots relative to the Northeast amendment untilled control, even though the North amendment plot mean shows a drop after treatment and a continued decline post-treatment (not evident in the East amendment plot). Correspondingly, the power of the BACI tests with or without less collocated plots are low with regard to copper (15 to 30%, see Section 7.2), and there is uncertainty associated with conclusions of no effect of tilling.

The same analysis used for total copper was employed to evaluate the effect of tilling on pCu using the Northeast amendment plot as the only reference plot. The Northeast amendment plot was limed, however, which can potentially increase pH and influence pCu. Therefore, this analysis evaluates if tilling contributes beyond the effect of the lime on the Northeast plot. The tilled plots tended to increase in pCu more than the increase in the untilled plots (**Figure 4b**), but the interaction term was not significant (**Table 19b**). The tilled plots exhibited significantly higher pCu than the untilled plot, but this occurred both before and after treatment (**Table 19a**). Thus, tilling had no significant effect on pCu. A confounding factor is the steeper slope of the Northeast plot, which was limed but not tilled, and the difference in the steepness of the plots may be influencing results, not just the tilling difference. Additionally, the power is weak for these alternate pCu tests (about 30% for interaction term with standard deviation of 1.07), creating uncertainty around this result. The original BACI with adjacent and less collocated reference plots produced similar conclusions (**Tables 9a** and **9b**), whereby the tilled plots tended to increase in pCu more than the increase in the untilled plots (**Figure 4b**), but the interaction term was not significant. Possibly, the lack of significance in the BACI is due to low power, but both tests give similar results, with significance at an 80 to 82% confidence level. Because copper is highly variable, detecting changes in copper or pCu from the treatment is not possible without more sampling. The graphs on **Figures 4b** and **5** also do not show any clear indication of beneficial effect of the treatments on pCu in any of the amendment plots in 2013, because they have similar pCu in the reference and amendment plots in 2013, or the difference between amended and reference plots in 2013 is about the same as in early 2008 before amendments were applied.

Overall, the alternate analyses support conclusions of the original BACI analyses that treatments did not significantly affect copper or pCu. However, the pCu results are highly uncertain because although pCu improved after amendments and tilling, power to detect whether the improvement was significant was poor.

7.4 Use of ERA Data

Using ERA plot data in soil comparisons (e.g., BACI) could create uncertainty because they represent a dataset that averages lower copper concentrations and higher pH than the data from the amendment study area. Therefore, use of ERA data was limited to locations with depressed pH (<5.5) and then used only as supporting information in graphs and tables for interpretation purposes only, and never combined with amendment data in any analyses, with one exception. The exception was one ERA plot (ERA-2) used as a less collocated reference for the East plot. The ERA-2 location was used because it is a rocky, relatively flat site dominated by mesquite with low pCu (4.1; **Appendix B-15**), very similar to the East reference plot (see **Appendix B-21**).

7.5 Persistent Effects of White Rain on pH and pCu

Current results indicate that the white rain had a beneficial effect on pH and pCu. However, 5 years may not be long enough to evaluate persistence trends for the white rain and amendments with certainty, and 5-year monitoring as part of the FS will indicate if persistence of the white rain observed to date is sustained. Additionally, data are variable, particularly for the Northeast plot, making persistence more difficult to detect or not detect when downward fluctuations lead to values similar to those seen before the white rain event.

Note also that if the white rain (which added lime to the soil) is not persistent, then liming may not be an effective remedial alternative, at least for the amount of lime delivered by the white rain. However, data to date suggest that the white rain is persistent and by extension, liming at the level of the white rain (see white rain report, Arcadis 2017a) may be effective in raising and sustaining pH where pH is low.

For pCu, copper declined since 2010 (with statistical significance) in many areas in the site including the amendment locations (Arcadis 2017a). Along with pH increasing in the East reference plot, this copper decrease may be contributing to the continued increase in pCu over time in both of the reference plots; however, copper levels in soil demonstrate high variability, making this possibility uncertain. **Figure 4a** shows that copper concentrations decreased and pH increased in reference plots (except West plot) between the pre- and post-periods, which supports the likelihood of attenuation due to the effect of the white rain combined with other possible factors that may have reduced copper, including cessation of the smelter operation in 2002 and subsequent surface erosion of copper from surface soils (no longer being replaced by smelter deposits). Although the East reference plot is trending upward and might reach the pre-FS RAC, this is not guaranteed or very certain given the variability observed in estimated pCu from 2006 to 2013 (**Figure 4a**), but should be considered when evaluating remedial alternatives.

7.6 Persistent Effects in Soil Chemistry of Treatments

High variability in concentrations over time results in uncertainty in the ability to detect small changes over time, particularly in the differences in pCu between plots. The difference in pCu between treated and reference plots may or may not be real, and tests had too little power to state which was the case conclusively. The difference nonetheless was used to evaluate persistence of treatment effects, in case they were real.

The appearance of a diminishing difference between the amendment and reference plots in pCu observed in the East plots (**Figure 4b**) is important and could indicate a “lack of benefit” of the amendments and tilling. These results could indicate that liming, tilling, and organic matter application is not very effective or needed because natural attenuation would have had the same effect on soil pCu 5 years after the white rain, as shown by the untreated East reference plot. However, the North plot results present a different conclusion. The regression slope (trend) for pCu is not significantly different than zero for the difference in the North plots (P = 0.327), indicating no significant change over time (**Figure 5**) and possible persistence. However, the North amendment plot declined in pCu slightly in 2013 during the last two sampling periods (see **Figure 4b**), which though not significant, creates some uncertainty as to the effectiveness of the treatments in that plot in the last year. The plot still exhibits pH above 5.0 (above the pre-FS RAC) after 5 years. There is uncertainty in identifying small changes over time in the North plot, given the observed variability, and that the effect of tilling, adding lime and organics to soils that already have relatively high pH may not be that detectable relative to reference plot changes. Additionally, persistence of pCu changes from the amendments and tilling was only evaluated for 5 years, and one cannot predict with certainty the persistence longer than that. The East plot results suggest natural attenuation may be as effective at changing the soil pCu as the treatments if given enough time. The North plot results, which show no significant trend in the pH difference, do not support nor refute that conjecture. The Northeast plot pCu shows no significant slope in the difference over time either, but its final pCu is very similar between the reference and amendment plots and as discussed previously, showed no benefit from treatments. Overall, uncertainty exists as to whether treatments changed the soil chemistry enough to provide any benefit, and persistence of the benefit may be a moot point.

Factors that add to the uncertainty of the persistence are that the North amendment plot for pH before treatment was not the same exact plot after treatment (moved 100 feet) and for copper, all reference plots before treatment also were not in the exact adjacent reference plot, but were in less collocated plots nearby (see **Section 7.1**). Also, in the early years, a sample size of two to three was too small to estimate mean copper concentrations with much precision before and immediately after treatment, even if in the same plot (see **Section 7.3**). Overall, the conclusion was that pCu results from the BACI analysis suggest that the treatments may not be beneficial in terms of improving the locally heterogeneous soil pCu, though pH was improved slightly when lime was tilled into the soil. This conclusion is uncertain given the short time frame of the study and variability in the data.

7.7 Dormancy Bias

The pilot study was not designed to evaluate change in plant copper uptake, and the pre-treatment tissue samples were collected in a different season (dormant season) than the post-treatment samples; therefore, there is much uncertainty in the results and interpretation due to a dormancy bias. Adjustment for the dormancy bias was performed nonetheless to facilitate interpretation of changes in plant uptake of copper to inform decisions for the Feasibility Study.

Copper concentrations measured in senesced vegetation in the winter dormant period were adjusted to growing season concentrations using a bioaccumulation model developed with ERA data (**Appendix B-7**). The use of a model to allow comparisons of data carries a number of associated uncertainties. First, comparison to an ERA bioaccumulation model in **Appendix B** required estimating proportion of grasses and mesquite biomass in leaves vs. seeds because ERA tissue concentrations were not reported for the whole plant. The proportions were assumed to be 15% of biomass for seeds of grasses and 5% of biomass for pods of mesquite, based on the literature (see footnote in **Table 7**) and field observations.

Second, the copper concentrations appeared to be biased high during the dormant season and were adjusted downward by 35% to remove the bias based on the bioaccumulation model. The literature supports that copper can be higher in senesced vegetation than growing vegetation for grasses on a mine site. In a paper that described copper sampling at a mine site in England with elevated copper (Hunter et al. 1987), tissue concentrations in grass species were much higher in the dormant season, possibly because copper moves into plant cell walls and can become more concentrated as cytoplasm is lost when the plant cell dries or freezes, a process observed in trees (Koelling 1996, Lyons et al. 2012).

However, some studies of herbaceous plants in areas without elevated copper show copper moving into the seeds and roots just before the dormant season or as leaves senesce, which produces a lower copper concentration during the dormant season (Himmelblau and Amasino 2001, Mira et al. 2001, Sankaran and Grusak 2014). Copper could also leach from leaves during winter from precipitation, resulting in lower concentrations. Though precipitation during the months of November to mid-March 2008 was minimal (0 to 0.1 inch, Hurley weather station), the differing results of these group of studies in the literature indicate uncertainty as to whether copper actually was biased high in the senesced vegetation.

Both the unadjusted and adjusted concentrations are presented in this report because of this uncertainty, though conclusions are based upon the adjusted concentrations. The conclusions on the effect of the white rain and amendments on copper uptake should be interpreted with caution, as the effect may be much larger or could be smaller than reported with the adjustment.

7.8 Long-term Effects of Amendments on Vegetation

Long-term recovery in the vegetation to its pre-white rain condition or natural condition is uncertain. It may be so slow that it offsets any benefit of reducing copper uptake, particularly for fair rangeland plots that lost their grasses. However, many uncertainties are associated with evaluating effects on vegetation because of limited data, other factors that affect vegetation in the field, and the study was not designed well to separate effects. The CCA was used to identify if some species are responding more to chemical than physical factors but the CCAs carry inherent uncertainties that have the potential to lead to erroneous conclusions. The CCA is dependent on the few plots used to develop the CCAs. If more plot data were obtained, the relationships may shift. The many uncertainties associated with the vegetation results and interpretation are discussed in **Appendix B-21**, which brings in information and data from other studies to help reduce the uncertainties, when possible.

The overarching conclusions for the vegetation uncertainty are that any remediation undertaken on the STSIU should be considered carefully as to its: 1) slow rate of recovery of the vegetation after disturbance that may not offset the benefits and 2) variability in copper and pCu making detecting differences or areas needing remediation difficult. Unless an area is overgrazed and mostly barren with some mesquite, remedies evaluated in this report may not produce any easily detectable benefit now that the white rain has occurred. This leaves few options for remediation. Scraping off topsoil with low pCu of fair rangeland areas without seeding could create poor rangeland conditions that may never have grasses recover to original levels[34]. Natural attenuation may be the best alternative, even for overgrazed barren areas that already have little topsoil because the pCu may be improving over time (see East and North reference plots, but more years of monitoring are needed to determine if they continue to improve to meet success criteria). The improvement on untreated areas in more recent years may be from mini-white rain events that some local individuals in a Chino working group have observed since the large white rain event in 2008. The possibility of doing more harm than good is of concern given the large uncertainty in

---

[34] The top 2 to 3 inches were removed of the golf course (Arcadis 2014), which may have set this fair rangeland area back to an earlier successional stage, but the vegetation was not surveyed before removal to evaluate changes. The site was seeded, however, and showed less annual weedy dominance and more perennial grasses than the unseeded amendment plots.

the outcome of the amendment study and known length of time it takes for vegetative succession in arid areas to recover the community from disturbance (**Appendix B-3**). If topsoil is lost, the area may never recover to original levels in fair rangeland areas.

7.9 Effect of Climate on Results

In arid environments, climate can have an effect on vegetation growth or cover and to a lesser extent on species richness, particularly of annual species (Yan et al. 2015, Zhang et al. 2016). Plant communities in arid areas tend to be somewhat resistant to droughts (Miranda et al. 2011), but the climatic variation creates some uncertainty in the amendment results. Though vegetation trends in the amendment plots were interpreted relative to changes in the adjacent reference plot to reduce climatic influences on the results (both are subject to same climate), climate could interact with the treatment in a way that creates larger changes in wet periods than dry periods. Possible climatic interactions are described below by first identifying climatic trends during the study, and second, identifying correlations between climate and vegetation parameters.

Based on Hurley records, **Figure 16** displays the average annual temperature and precipitation during the monsoon months of July, August, and September, when most vegetation growth occurs. Because the temperature trend appears to vary inversely with the monsoon precipitation (rainfall), precipitation trends can represent the climatic influences, especially given the area is an arid semi-desert with water limitations for plant growth.

Figure 17 overlays precipitation trends during the 3 months before each sampling period on the trend of the non-woody vegetation cover. Of the vegetation parameters, non-woody cover percentages exhibited the best correlation to precipitation. This figure shows that the non-woody cover in the pairs of East, North, and West plots was strongly affected by the precipitation pattern, and the Northeast plots were less influenced (**Figure 17**). In particular, the East and North plots most closely paralleled climatic trends, likely because they had the highest proportion of cover in herbaceous vegetation (**Figure 10**). Woody vegetation is less responsive to rainfall than herbaceous plants, and herbaceous annual species are the most responsive (Miranda et al. 2011). Seasonal weather patterns also influenced the vegetation results. The spring sampling periods (March 2008, April 2010) exhibited consistently lower percent cover of herbaceous plants than the fall growing seasons due to senescence of leaves and shoots in the dry early spring. In contrast to the strong effects observed on non-woody cover, climatic or seasonal changes did not have an obvious effect on richness or other diversity measures.

The changes due to precipitation can create uncertainty in the interpretation of the vegetation cover results in two ways. First, the amount of precipitation can change the magnitude of the difference between the treated and reference plots. The control West plots were not treated, and as such, could be evaluated to determine if meteorological conditions alone were expanding the inherent difference in non-woody cover between the two plots more in the rainy fall than in the drier spring. The answer was “no” when all autumn periods were compared to spring 2008, but “yes” when compared to spring 2010, when the difference was much smaller than in the fall (**Figure 10**). Fortunately, spring 2008 was the pre-treatment period being compared to fall 2013 in **Tables 16a** and **16b** to detect treatment effects, and as such, no strong bias from precipitation differences is expected.

The second way precipitation can influence results is by creating large variability in the vegetation community data, making interpretations uncertain (particularly for vegetative cover in North and East amendment plots, see **Table 16a**). For example, the East amendment plot percent cover increases from amendments and tilling only when the anomalous spring 2010 estimate is ignored. After tilling and amendment application, the East plot became dominated by non-woody, herbaceous vegetation that decreased greatly during the dry season in spring, a trend that did not occur during spring 2008 when woody vegetation dominated. The spring 2008 community represented the community that grew during the growing monsoon season in 2007 and represented the pre-white rain condition. The low precipitation in spring 2010, with its loss of woody vegetation, created variability in the dataset that had to be removed to properly interpret effects.

Precipitation patterns can also affect species composition. Including precipitation and season in the CCA (**Figure 13c**) did not considerably change the CCA or conclusions on species composition (compare to **Figure 13b**). However, the wetter years appear to be influencing vegetation composition more than drier years, with more cover by annual and perennial forb species during wet years. **Figure 16** shows that 2011 and 2012 were drought years. During these 2 years, vegetation was not sampled, though photographs were taken (**Appendix D**). Because these 2 years were missed, the CCA does not fully capture precipitation effects on herbaceous species composition.

The similarity in non-woody cover before and after the drought support that the drought during those years did not have a large effect on non-woody cover once rainfall returned to normal. However, annual herbaceous plants increased in abundance during the wet year of 2013, consistent with other studies in arid environments (Yan et al. 2015). The annual forb (carelessweed) invaded in abundance during the wet year of 2013, particularly in the North amendment plot, possibly because of the drought in the 2 years prior, creating more barren locations for such weeds to invade. In the photolog (**Appendix D**), the 2011 photos of the North amendment plot show a much more barren area than in 2010, which is not very noticeable in the other plots, whether they are reference or amendment plots. Tilling fair rangeland in the North plot may have made it more susceptible to losing cover during drought and being invaded by annual weeds when the drought ended. This may not have been observed in the East amendment plot because it already was mostly barren (mostly mesquite) and could only improve regardless of the weather conditions. Possibly the North amendment plot may have shown greater improvement if no drought had occurred. The vegetation is responding to confounding climatic factors that are difficult to tease apart, and as such, there is substantial uncertainty in the factors causing the trends observed.

Because no areas in the study were not subjected to the white rain, climatic effects were more difficult to separate when evaluating white rain effects alone on the plant community. To adjust for climatic effects, graphs (e.g., **Figures 9a** and **9b**) were evaluated qualitatively, comparing pre-white rain conditions in spring 2008 to the same season in 2010, after considering that the growing season for those dormant spring periods the fall before was drier for the 2010 than the 2008 community. If conclusions were the same with this comparison for the majority of the plots as when climate differences were ignored (which was the case), then the climate effects were assumed to not influence the results enough to be of concern.

7.10 Summary of Uncertainties

This study was not optimally designed to answer questions of interest for the FS. The decisions for the FS will be better informed, however, using results from an uncertain study with adjustments and assumptions rather than having no information. Adjustments and assumptions were made to use this long-term dataset, which encompasses the years 2006 to 2013.

The adjustments to the soil chemistry data included adjusting the data to represent sieved data for years when not sieved, deleting SPLP data with 1:20 dilution ratio (only those with 1:5 ratio retained), using post-white rain copper soil data in May 2008 (or 2010 for west plots) to represent pre-white rain soil copper in 2006 (assuming that white rain did not change copper concentrations), using less collocated data to evaluate if changes were different from regional trends in the early years, and using an equation to calculate pCu.

For tissue data, the adjustments were an unwashed to washed adjustment applied to 2008 data and a dormancy bias adjustment for that year. ERA data in a bioaccumulation model were used to develop the dormancy bias, and uncertainty exists as to their representativeness for the soil to plant bioaccumulation regression expected on the amendment plots. The ERA data with pH < 5.5 were included on **Figure 6** as a comparison, but again, uncertainty exists as to the appropriateness of using ERA data for this comparison. Locations with soil having pH < 5.5 generally responded to the white rain in a way similar to that of the amendment plots, and for this reason, only those ERA plots were included.

Additionally, plant tissue data were not collected in reference plots in the pre-treatment period, nor were they collected again until the end of 5 years. Treatment effects had to be restricted to comparisons of amended and reference plots in the last year, assuming there were no plant concentration differences between plots before treatment.

Plant community data were collected on the reference plot before the white rain and periodically thereafter, but were not replicated on the reference plot (n =1), which meant that no statistical analysis was possible. These adjustments and data gaps make the results and conclusions of this report uncertain. Additionally, the three remedies (lime, organic matter, tilling) were not separated, which confounds decisions about whether some components of the treatments should be included or excluded for remediation. Chino drew from information from other studies (white rain report, phytotoxicity and community study), anecdotal information (haul road ripping), and literature to assist in providing additional information that can help separate out the effectiveness of the three treatments (lime, tilling, and organic matter), as described in **Appendix B-21**. Final conclusions are drawn from this study with the understanding of the high uncertainty in the results due to the adjustments required to work around the various data gaps.

8. Evaluation of Remedial Technologies Separately

Appendix B-21 discusses the effectiveness of each remedial technology separately in changing the primary metrics of pCu, copper uptake, cover, richness, and species composition (successional stage and grass proportions) if such information is available for each metric. Information from the sitewide ERA (Newfields 2005), white rain report (Arcadis 2017b), phytotoxicity and community study (Arcadis 2017b), and haul road ripping project were reviewed to develop the conclusions and recommendations in **Table 18** for liming, tilling, and organic matter applied separately in three categories:

1. Poor rangeland with rocky soils in relatively level areas (< 6% slope on topographic maps, see **Figure C-2-2)**
2. Fair to good quality rangeland with granular soils in relatively level areas
3. Fair to good quality rangeland on steeper slopes.

Category 1 is represented by the East location, Category 2 by the North and West locations, and Category 3 by the Northeast location.

The assessment revealed that liming alone, as seen by the effect of the white rain on all three soil categories, can increase soil pH and pCu; decrease copper uptake into plants; and increase species richness and the proportion of cover in non-woody plants (also see main text). The increase in soil pH and pCu is smaller on the steep plot because of runoff. On all the plots, effects on cover, grass proportions, and successional stage appear to be at most minimal (**Table 18**).

Tilling has different effects, depending on whether it occurs in poor rangeland or fair to good rangeland areas (**Table 18**). Tilling in the eroded rocky soil type characterized as in poor rangeland condition increases grass cover to a much greater extent than lime alone. The grass species present after tilling include more late successional species over time than if the area is not tilled and only subjected to the white rain. However, tilling in fair rangeland reverses positive trends of the white rain and causes a reduction in diversity and percent in grass cover after 5 years. This reduction is not unexpected because a granular soil located in an area with fair rangeland condition does not need decompacting and would already have good grass growth, as long as low pCu was not too limiting. The North amendment plot had acidic soil with low pCu (estimated to be about 2.0) during the growing season before the white rain, yet grass species and plant diversity in the plot were lost after the treatment. The evidence supports that copper uptake in plant tissues is less of an impediment to a healthy grass and rangeland community for fair rangeland than disturbance that can set succession back to an earlier stage.

Organic matter may do more harm than good to rangeland and wildlife habitat. The literature supports that organic matter is often of little benefit when reclaiming soils, often decreases species richness, and increases invasion by annual weedy species. Some plots lost vegetative cover and all lost desirable grasses, possibly from the organic matter additions, though this is uncertain. What is certain is that desirable grasses returned in the tilled haul road without organic matter applied, and considerable amounts of organic matter (manure) were observed moving downhill off the steep plot, providing little benefit (**Table 18**).

Recommendations by soil category (categories shown on **Figure C-2-2)** are as follows:

1. Poor rangeland with rocky soils in relatively level areas (flat rocky):
   - Tilling is recommended in areas of depressed pCu, pending further evaluation in the FS.
2. Fair to good quality rangeland with granular soils in relatively level areas:
   - No remedy was effective in increasing cover of desirable species enough to improve wildlife habitat and livestock range. Therefore, none of these three remedies are recommended.
3. Fair to good quality rangeland on steeper slopes:
   - No remedy was effective in increasing cover of desirable species enough to improve wildlife habitat and livestock range. Therefore, none of these three remedies are recommended.

9. Conclusions and Recommendations

This Year 5 Monitoring Report presents the final results of the STSIU Amendment Study that evaluates the effectiveness of three remedial techniques: tilling, liming, and organic matter application. The effect of the natural white rain event and subsequent natural attenuation, the effect of tilling via haul road ripping, and results from other studies were considered together to develop the final conclusions and summary of recommendations herein.

This study first identified the primary metrics important for assessing success of a remedial technique and found the following:

- Soil pCu is the soil parameter most strongly correlated with plant uptake of copper and thus is a possible indicator of potential adverse effects on the plant community. It is a key primary metric to evaluate effectiveness of the different amendments, and its interpretation was supported by data on pH, total copper, TOC, and ABA analysis. Soil pCu has been used to assess the need for remediation when vegetation data are unavailable (e.g., the pCu STSIU pre-FS RAC), but vegetation community metrics are more important when evaluating remediation effectiveness.

- Soluble copper is not as useful an indicator of soil toxicity as pCu because it includes copper complexed with dissolved compounds that are not readily available to plants. Moreover, these compounds may increase with additions of organic matter, resulting in soluble copper increasing after remediation. Therefore, no target soluble copper criteria should be established for success.

- Copper uptake, as represented by copper concentrations in aboveground plant tissue, is a key parameter in determining exposure to plants in addition to the soil pCu. The soil pCu does not represent all bioavailable copper that may be taken up into a plant. The aboveground tissue concentrations, if high, indicate plant absorption of copper, which may have a toxic effect. However, copper may not translocate from the roots to shoots in some plants and evaluating both the soil pCu and tissue copper concentration metrics provides a more complete picture of exposure. Therefore, tissue copper was also considered an important primary metric along with soil pCu for assessing remediation success.

- The most ecologically relevant primary metrics are plant species richness and percent vegetative cover, two indicators of wildlife habitat and rangeland quality that need to be protected. An evaluation of species composition was used in conjunction with richness and cover to determine if the remediation improved the quality of the plant communities for wildlife and livestock after reducing copper uptake into plants. Notably, richness can increase with a few small plants of different species, and yet wildlife and livestock forage and cover may not improve enough in the area to make a difference in habitat quality if the new species are small and sparse. Therefore, improvement of total vegetative cover composed of desirable species (in particular perennial rangeland grasses) is the most ecologically important target.

The main conclusions from the Amendment Study are as follows:

- The white rain event, and subsequent natural attenuation, was effective at: (1) improving pCu in low soil pH areas (< 5.5) across the STSIU; (2) reducing bioavailability and plant uptake of Cu; and (3) improving plant community richness. It was particularly effective on the relatively level areas, whether poor or good rangeland. The pH monitoring program (Arcadis 2017a) evaluated the persistence of the improvement in pH and pCu from the white rain, and demonstrated that the improvement has been sustained after 5 years, consistent with the results of this study. Low pCu plots in the relatively level areas improved to pCu above 5 or near 5. In areas exhibiting continual improvement in pCu, monitoring natural attenuation is recommended as the best remedial technique. More years may be needed to statistically demonstrate if pCu is increasing in some areas. While the white rain event did not result in the establishment of plant species that are potentially toxic or of low value to wildlife or livestock, vegetation cover was not increased enough to show benefit to wildlife habitat or improved rangeland quality. Overall, lime alone does not appear to change the community enough to enact the plant community changes desired.

- While the white rain event was effective, the remedial technologies applied after the white rain were not as effective above and beyond the white rain effect. When all three technologies were combined (lime, organic matter, tilling) on the relatively level plots, pH was increased (with 90% confidence). However, the three technologies did not significantly improve soil pCu. Possibly the lack of significant change in pCu overall may have been due to high variability in pCu resulting from heterogeneity of the field soils, sampling error, analytical error, and using an equation to calculate pCu. In parallel with the insignificant change in pCu, reduction in copper uptake into plants from the three technologies combined also was minimal as the white rain was responsible for most of the reduction in the copper uptake. Tilled plots (to 8 inch depth) did not show improved pCu relative to untilled plots in the study. The effect of tilling deeper (to 12 to 18 inches) on the plant community was demonstrated by an example outside this specific study. A haul road traversing poor rangeland condition with no vegetation initially was tilled, and that action did result in high abundance of diverse grasses after 11 years. This example supports the concept that vegetation changes could be from decompacting the soil on the road. The finding on amendment plots of no clear benefit of all three treatments (in increasing pCu and decreasing uptake of copper in plants after the white rain) suggests that chemical changes from mixing are not the driver of the large community changes, but rather the tilling physically decompacts soil, allowing plants to re-establish on poor rangeland. In contrast, the fair rangeland on relatively level ground undergoing the same treatments did not increase in cover or richness and reversed succession toward an earlier seral stage with loss of grasses. The fair rangeland plot on steeper ground also experienced a setback in succession to an earlier stage with a loss of desirable grasses. Unlike the poor rangeland plot, these areas already had a diverse plant community and rangeland grasses present, even before the white rain, despite a low pCu of approximately 2 to 3 at that time. The benefit from decompacting soil by tilling is large and should be considered as a remedial technology. However, it is warranted only if erosion of surface soil resulting in a compacted or rocky surface was caused by a loss of the roots of a plant community impacted by pCu in the past, rather than from overgrazing.

- Organic matter, in combination with the other one or two technologies, did not improve pCu or reduce copper uptake significantly. Organic matter may have exacerbated annual weed invasion and slowed recovery after the plots were disturbed from tilling or amendment application. Unlike the white rain effect alone, the disturbance from tilling combined with the effect of applying amendments in the form of lime and organic matter increased undesirable annual weeds substantially (e.g., golden crownbeard, carelessweed), some of which are potentially toxic to livestock. Weeds increased less on the steep plot that was not tilled but also less on the haul road that was tilled, which suggests factors other than tilling may have increased invasion of undesirable weeds; however, organic matter may not be responsible because organic matter was applied at high amounts on the steeper plot with less weed invasion, and was not applied at all on the tilled haul road that also experienced less weed invasion. The plot with less invasion was steep and subject to runoff of the organic matter, which may explain why it experienced less invasion than the more level plots that were also subject to application of organic matter. The weed invasion may be short-term, as seen on the haul road that was tilled. However, after 8 years, the fair and poor rangeland plots on relatively level ground still support a fair amount of potentially toxic annual weed species. Organic matter added to soils for reclamation rarely have been shown to be beneficial in arid or semi-arid areas.

- The three remedial technologies at the levels evaluated in this pilot study are not viable for increasing pCu in steeper areas ($\geq$ 13% slope). Tilling is not a feasible method for slopes too steep or too rough (high amount of boulders) for the equipment. It is also not feasible for bedrock areas. Liming and organic matter application were not effective at increasing pCu on steeper areas, which generally are in fair rangeland condition in the STSIU. Even the lime in the white rain had only a small effect on pCu on the steeper areas.

- The results support the following recommendations:

  - Liming and tilling is only recommended in relatively flat, poor rangeland rocky areas where phytotoxicity from copper can be demonstrated. Tilling alone has been shown to be effective, and should be tried first at an 8-inch depth and deeper to evaluate the proper depth.

  - Organic matter application is not recommended.

In summary, the white rain increased pH and pCu significantly and reduced copper uptake into the plants of all the plots. As a result, the treatments added to the soil in the plots provided minimal if any additional benefit in further reducing copper impacts to the plant community because the white rain already significantly improved the soil chemistry. The white rain increased plant species richness, but had a small effect on total plant cover that is required to benefit wildlife and livestock. The tilling and mixing of lime amendments into the soil tended to increase pH but degraded the plant community on the fair rangeland plot and improved the plant community on the poor rangeland plot. Recovery of degraded conditions could take decades. The weight of evidence supports that, on plots such as the ones in this study with high copper (up to 2,900 mg/kg) and low to moderate pH after the white rain (as low as 3.9 in one year in steep sloped plot and as low as 5.7 to 5.9 in flatter plots), the treatments applied will likely produce no easily discernible benefit in terms of reducing current phytotoxicity. The benefit of remediation likely will be greatest in decompacting soils that may have been eroded and degraded long ago from smelter or tailings impacts that destroyed the historical plant community.

This pilot study is an initial assessment of the effectiveness of these three remedial techniques, and these conclusions and recommendations were considered in combination with findings from other relevant STSIU studies (Arcadis 2011a, 2014, 2017a, 2017b) to determine remedial actions that should be advanced to full-scale implementation via the FS. Guidelines for remediation of different soil categories on the STSIU from this assessment are based on obtaining a net environmental benefit and are as follows:

1. Poor rangeland with rocky soils in relatively level areas (flat rocky soils on **Figure C-2-2**) that are impacted by pCu:

    - Tilling is recommended in depressed pCu areas, pending further evaluation in the FS.

2. Fair to good quality rangeland with granular soils in relatively level areas (flat granular soils on **Figure C-2-2**)

    - Technologies evaluated in this study are not recommended.

3. Fair to good quality rangeland on steeper slopes ($\geq$ 13 percent):

    - Technologies evaluated in this study are not recommended.

As more information becomes available during the FS process, these recommendations may be revised, and should be considered preliminary.

Table 1
Chronology of Study Design Modifications and Implementation Showing Amendment Plot Specifications - Original and Revised

Year 5 Amendment Study Monitoring Report
Freeport-McMoRan Chino Mines Company
Vanadium, New Mexico

Chronology of Study by Plot Location and Changes (changes are italicized)

Study Design in 2006 (finalized 2008) Study Plan									Pre-White Rain Sampling in 2006
Plot	**Baseline Conditions - Pre-white rain**			**Plot Amendments Originally Planned**				**Installation Date**	Baseline pH, TOC, and C:N ratio sampled in July 2006 No reference plots sampled
	Slope (aspect)	**Rangeland Condition in 1997**[1]	**Baseline pH/pCu 2006**[2]	**Date Planned of Amendment**	**Lime Slurry Application Rate** (t/ac as $CaCO_3$)	**OM Addition/ Rate** (t/ac)	**Application Method**		
West	6% (SE)	Fair-Good	6.49/5.06	June 2008	2	none	Spray Only	July 2006	White rain event in January 2008 changed design
North	6% (E)	Fair	3.69/2.04	June 2008	6.6	10	Spray and Till	July 2006	
Northeast	52% (S)	Fair	5.41/3.26	June 2008	2.5	none	Spray Only	July 2006	
East	5% (E)	Poor	4.55/3.5	June 2008	6.6	20	Spray and Till	July 2006	

Study Design Revised in March 2008 after January 2008 White Rain									Post-white Rain and Post-Amendment Sampling
Plot	**Baseline Conditions - Post-white rain**			**Plot Amendments Planned after White Rain**				**Installation Date**	Baseline soil chemistry (pH, Cu, SPLP Cu, TOC, C:N, Ca, K, NH_4^+, TKN, NO_3^-/NO_2^-) sampled and analyzed in lab in early May 2008 except Cu in West plot (n = 2 each) Baseline field paste pH of soil sampled in 4 plots in late May/early June 2008 (n = 10 each)
	Slope (aspect)	**Rangeland Condition in 1997**[1]	**Baseline pH/pCu 2008**[2]	**Date of Amendment**	**Lime Application Rate** (t/ac as $CaCO_3$)	**OM Addition/ Rate** (t/ac)	**Application Method**		
West (control)	6% (SE)	Fair-Good	*8.16/5.91* [3]	NA (became a control)	*none*	*none*	*NA*	July 2006	All four amendment plots sampled for soil chemistry (pH, Cu, SPLP Cu, TOC, C:N, Ca, K, NH4+, TKN, NO3-/NO2-) post-amendment semi-annually, starting December 2008 extending to October 2013. Acid Base Accounting (ABA) conducted once in December 2008
North (Baseline Amendment Plot, Post-amendment Plot[4])	6%, *8%* (E)	Fair	*6.61/4.31*	*6/17/2008*	*1.3*	*24*	Spray and Till	July 2006, June 17, *2008*	
Northeast (Baseline Amendment Plot, Post-amendment Plot)	52%,*14%* (S)	Fair	*5.92/3.50*	*6/18/2008*	*1.3*	*72*	Spray Only	July 2006, May *2008*	Baseline vegetation community parameters (non-CCP methods) and tissue sampled in the four amendment plots in March 2008. Vegetation community parameters (non-CCP methods) sampled post-amendment on these four amendment plots in December 2008, and in October 2009, April 2010, October 2010, October 2013. Tissue sampled post-amendment only in Fall 2013. CCP methods added to non-CCP methods of sampling in fall 2010 and fall 2013.
East	5% (E)	Poor	*5.68/4.61*	*6/17/2008*	*1.3*	*47*	Spray and Till	July 2006	

Study Design Revised in March 2008 after January 2008 White Rain -- by adding Reference Plots									Post-white Rain and Post-Amendment Sampling
Plot	**Baseline Conditions - Post-white rain**			**Plot Amendments Planned and Implemented after White Rain**				**Installation Date**	Baseline Vegetation community parameters sampled on reference plots in March 2008 in dormant season (thus representing pre-white rain community growth). Vegetation sampled post-amendment on reference plots in December 2008 for all four plots, and in October 2008, April 2010, October 2010, October 2013 for all plots. Tissue sampled in October 2013. No CCP methods used on reference plots.
	Slope (aspect)	**Rangeland Condition in 1997**[1]	**Baseline pH/pCu 2008**[2]	**Date of Amendment**	**Lime Application Rate** (Tons/acre as $CaCO_3$)	**OM Addition/ Rate** (Tons/acre)	**Application Method**		
West Reference (control)	*6% (SE)*	Fair-Good	*8.05/6.07* [3]	NA	none	none	NA	*March 2008*	
North Reference (Baseline Plot, Post-amendment Plot)	*12%, 13% (E)*	Fair	*5.88/4.43* [3]	NA	*none*	*none*	*NA*	*March 2008/ mid-June 2008*	Baseline field paste pH of soil sampled in late May/June 2008 (n = 10 each)
Northeast Reference (Baseline Plot, Post-amendment Plot)	*50%, 28% (S)*	Fair	*5.50/3.41*	NA	*none*	*none*	*NA*	*March 2008/ May 2008*	
East Reference	*4% (E)*	Poor	*4.92/3.59* [3]	NA	*none*	*none*	*NA*	*March 2008*	ABA, soil analytes other than pH, aand plant tissue not sampled on reference plots during post-white rain baseline period so unavailable for 2008 baseline.

Table 1
Chronology of Study Design Modifications and Implementation Showing Amendment Plot Specifications - Original and Revised

Year 5 Amendment Study Monitoring Report
Freeport-McMoRan Chino Mines Company
Vanadium, New Mexico

Reference Plots Redefined in 2010 to Include all Soil Chemistry Sampling									Post-Amendment Sampling Only
Plot	**Conditions of Installed Soil Reference Plots**			**Plot Amendments Applied**					Soil chemistry sampled for lab analysis (pH, Cu, SPLP Cu, TOC, C:N, Ca, K, NH4+, TKN, NO3-/NO2-) on reference plots semi-annually from April 2010 to October 2013 (in post amendment period). ABA also conducted annually from 2010 to 2013 (part of pH monitoring program).
	Slope (aspect)	**Condition in 1997[1]**	**First Post-Amendment pH/pCu April 2010**	**Date of Amendment**	**Lime Application Rate** (t/ac as $CaCO_3$)	**OM Addition/ Rate** (t/ac)	**Application Method**	**Installation Date**	
West Reference (control)	6% (SE)	Fair-Good	*8.03/7.73*	NA	none	none	NA	April 2010	
North Reference	13% (E)	Fair	*5.26/4.35*	NA	none	none	NA	April 2010	
Northeast Reference	28% (S)	Fair	*5.76/4.87*	NA	none	none	NA	April 2010	
East Reference	4% (E)	Poor	*4.16/3.23*	NA	none	none	NA	April 2010	

Notes:

1 - Preliminary rangeland condition from Woodward Clyde (1997). Observed apparent trend (OAT) scores based on remote-sensing-based maps described in (ARCADIS 2011a) and field estimate of West plot had similar ratings of "good", "fair-good", "fair-good", and "poor" for West, North, Northeast, and East plots

2 - Unless stated otherwise, pH averaged over all available data (field and lab, n = 12), sieved or adjusted as if sieved to < 2 mm. pCu is calculated using lab pH data and total copper. pCu is often an estimate because Cu not sampled on plots in 2006, on reference plots, or in West plot in 2008 (see text for estimati

3 - pH for these plots was based on average of 10 field samples (see **Appendix A**), which were only data available for these plots in 2008.

4 - red indicates applies to moved plot (due to erosion problems for North and too steep slope for equipment for Northeast). Before being moved plot was baseline plot and after being moved is called post-amendment plot (Figure 2).

t/ac = tons per acre
pCu = cupric iron activity

OM = organic matter
$CaCO_3$ = calcium carbonate

NA = Not available

Table 2
Hypotheses Tested as Part of the Amendment Study Conceptual Model

Year 5 Amendment Study Monitoring Report
Freeport-McMoRan Chino Mines Company
Vanadium, New Mexico

Hypothesis	Outcome
Effects of White Rain on Soil Chemistry and Plant Uptake of Copper	
Soil pH and pCu will increase, soluble copper will decrease, and plant tissue copper concentrations will decrease on amendment and reference plots as a result of the white rain that occurred in January 2008, and the effect will persist.	Supported: Results suggest that the white rain event that limed areas increased pH and pCu and decreased plant tissue copper concentration. The pCu increase has persisted. Not Supported: There is not sufficient evidence to support a reduction in soluble copper due to the white rain event.
Effects of Remedial Technologies on Soil Chemistry (7 hypotheses)	
No. 1: Amendment using lime (at 1.3 tons/acre for the North, Northeast, and East plots) with or without tilling will increase pH and the increase will persist and exceed the target pH of 5.5.	Partially Supported: Results suggest that lime and tilling, combined with white rain, increased pH initially to above target levels and that the increase has persisted. Lime added after the white rain did not increase pH in the steep-sloped, untilled plot.
No. 2: Tilling will decrease total copper in surface soil and the decrease will persist, whereas lime and organic matter will not affect total copper because copper will remain in the surface soils.	Supported: Results suggest that the application of lime and organic matter did not change concentrations of total copper. Not Supported: Evidence does not support a reduction in total copper due to tilling to 8 inch depth.
No. 3: Amendment of lime/organic matter and/or tilling will increase pCu, and this increase will persist and show benefit relative to untreated plots.	Increase Not Supported: Soil pCu did not significantly increase in the amended and tilled plots. Though means were higher in the tilled plots, statistical power to detect significant differences was low. Benefit is Not Supported: Though persistent over the five years, the insignficant increase in pCu in the amended, tilled plots relative to the reference plot in the poor rangeland plot is diminishing, rather than being sustained over time because the reference plot pCu is increasing. Not Supported: Evidence is insufficient to support an increase in pCu due to the application of lime and organic matter alone beyond the effects of the liming from the white rain. Soil pCu did not increase on a steep slope area (14% slope) treated only with organic matter and additional lime.
No. 4: Amendment of lime, organic matter, and tilling will decrease soluble copper and the decrease will persist.	Not Supported: Soluble copper increased significantly just after application of the remedial technologies, though the increase likely is part of large fluctuations observed through time.
No. 5: Amendment of organic matter will increase TOC percentage and decrease C:N ratio; these changes will persist, meeting the target of 1% TOC and C:N of less than 20:1, preferably between 8:1 and 15:1.	Supported: Results suggest that organic matter amendments increased TOC and decreased C:N ratio to target levels, though the East amendment plot decreased C:N ratio to slightly below the target threshold of 8:1. The changes persisted.
Effects of Changes in Soil Chemistry on Vegetation	
No. 6: The increase in pCu from lime/organic matter and tilling will reduce uptake of copper into plant tissue.	Not Clearly Supported: Soil pCu did not significantly increase from amendments and/or tilling beyond the white rain, and uptake correspondingly did not decrease much, if at all, beyond hte decrease resulting from the white rain. Though copper in the plants decreased to non-toxic levels, particularly in herbaceous vegetation (13 mg/kg, Figure 6, Table 7), most, if not all of the decrease, was probably from the white rain. Not Supported. Application of organic matter and lime alone did not reduce copper in tissue.
No. 7: The reduced uptake of copper will increase canopy cover and richness. It will also increase evenness and overall diversity of the plant community by 2013, and will change the community composition.	Not Supported for Poor Rangeland: Though canopy cover, diversity, evenness and richness increased on the poor rangeland area and the relative cover of the rangeland grasses increased (Table 16a,b and Figure 9a,b), little support exists for the assumption of a significant reduced uptake of copper or increased pCu causing the changes. Therefore plant community changes are likely due to physical (decompacting) changes, rather than chemical changes from the treatments. Not Supported for Fair Rangeland: Canopy cover and richness did not increase on the fair rangeland area with tilling and amendments (Figure 9a,b, Table 16 a,b). Evenness (Table 16a) or rangeland grasses (Table 16b) were reduced on all fair rangeland plots, and changes were likely independent of chemical changes, but rather a result of setting back vegetative succession to an earlier stage.

Notes:

C:N = carbon:nitrogen ratio

pCu = cupric iron activity

TOC = total organic carbon

Table 3
Closure/Closeout Plan (CCP) Reclamation Guidelines

Year 5 Amendment Study Monitoring Report
Freeport-McMoRan Chino Mines Company
Vanadium, New Mexico

CCP Performance Criteria after ~12 Years	Minimum Cover[1]	# Species
Total Canopy Cover (%)	38%	---
Shrub Density (shrubs/m^2)	0.5	---
Perennial Warm Season Grass Cover (%)	1.0%	3
Perennial Cool Season Grass Cover (%)[2]	0.5%	1
Perennial Shrub (%)	1.0%	2
Forbs (%)[3]	0.1%	1
Number of Species (total)	---	8

Notes:

1 - Minimum cover is the cover level of the individual species with the least amount of cover.

2 - For the purposes of this guideline, intermediate-season grasses, like plains lovegrass (*Eragrostis intermedia*), were considered the functional equivalent of the more traditionally defined cool season grasses.

3 -The forb guideline was unqualified with respect to seasonality and could include a perennial, biannual, or annual species.

CCP = Closure/Closeout Plan

m^2 = square meters

Oct-13	8/3[5]	7.64	1021	1.15	0.03	6.53	12

Notes:

1- All pH and total copper sample measured between 2006 and 2010 were not sieved but are adjusted to sieved (< 2 mm) concentrations using regression (see text). 2011 to 2013 data were sieved to < 2mm in laboratory.

2 - All SPLP Cu analyzed using modified 5:1 ratio with $CaCl_2$, except October 2011 to April 2013 used standard 1:20 ratio with DI water.

3- 2006 for Northeast and 2006 and Spring 2008 for North samples were collected from slightly different locations than December 2008 to 2012.

4 - Number before slash is pH averaged on two lab samples; number after slash is pH averaged on 12 samples (10 field paste pH and two lab samples). The exception is West amendment plot, where number is mean of field paste pH data for May 2008 (n=10) because no lab data were collected in May 2008.

5 - Eight samples were analyzed for pH, copper, and soluble copper by SPLP while three of the eight samples were analyzed for the full suite of constituents.
6 - Weighted average 0-1" and 2-4" samples to represent each 0-4" sample (depths are given in Appendix A, Table A-3).
mg/kg - milligrams per kilogram
mg/L - milligrams per liter
SPLP - Synthetic Precipitation Leaching Procedure
s.u. - standard units

pCu = cupric iron activity

-- = not applicable

Table 5
Vegetation Cover Daubenmire Class Midpoints

Year 5 Amendment Study Monitoring Report
Freeport-McMoRan Chino Mines Company

North, East, Northeast Amendment Plots only: (A) Tissue Cu 2008 vs. (B) Tissue Cu 20131	83	23	8, 11	t = 3.11	**0.0071**	59	9
Same as above row but with no mesquite[1]	83	16	8, 8	t = 3.57	**0.0041**	66	7
East and North Amendment Plots only: (A) Tissue Cu 2008 vs. (B) Tissue Cu 20131	68	20	7, 8	t = 3.69	**0.0033**	48	12
Same as above row but with no mesquite[1]	68	13	7, 6	t = 4.36	**0.0019**	54	7
Comparison in Space (washed data)							
East, Northeast, and North Plots only: (A) Reference 2013 vs. (B) Amendment 2013	33	23	11, 9	t = -1.22	0.1195	--	9
Same as above row but with no mesquite[1]	23	16	6, 8	t = -1.54	*0.0747*	--	7
East and North Plots only: (A) Reference 2013 vs. (B) Amendment 2013	32	20	6, 8	t = -1.25	0.1244	--	12
Same as above row but with no mesquite[1]	20	13	4, 6	t = -1.57	*0.0870*	--	7'[3]
Northeast Amendment Plot only: (A) Reference 2013 vs. (B) Amendment 2013	34	34	3, 3	t =- 0.011	0.2480	--	0
Same as above row but with no mesquite[1]	28	25	2, 2	t = -0.340	0.3919	--	3

Notes:

1 - 2008 data corrected for dormancy bias (35% decrease) and to represent washed tissue (multiply by 0.9282).

2 - subtracting the difference from the "white rain" from the difference from the "white rain plus treatments" is the increase beyond the white rain. It is the same as the difference between 2013 amendment and reference pl because the same 2008 pre-white rain plot is used to calculate the differences from it and each 2013 plot.

3 - More of this difference is attributed to the East plot (difference of 11 mg/kg) than to the North plot (difference of 3 mg/kg)

Bolded when P<0.05; italicized when P<0.10. When sample size for a group ≤ 6 (almost all comparisons in space), then alpha for significance = 0.10, rather than 0.05.

Snakeweed	63.00	42.21	39.18				

Notes:

1 - If 2013 were available only as unwashed to compare to washed, then adjustment made to unwashed using regression equation between washed and unwashed of y = 0.9282x (R^2 = 0.55, See Appendix B-2). Such calculated values are gray.

2 - All samples consist of one above ground composite sample (n = 1) that includes seeds and above ground foliage from one species (collected throughout the plot).

3 - Copper is adjusted to remove dormancy bias downward by 35 percent.

Values provided are milligrams per kilogram (mg/kg); plant tissue includes combined seeds and foliage. Scientific names of plants are in Appendix B-1.

Notes:

1- average of the average of categories (by plot type and sampling period), called least square mean.

BACI is a mixed model ANOVA with fixed factors of planned treatment of plot (reference vs. amendment plot) and time period (before and after treatment) and random factors of plot location and sampling period.

Excludes white rain effect (no 2006 data)

L - plot that either will have or has had lime added (and organics always added with lime, though at different rates).

till - plot that either will be or has been tilled.

Amendment - plots that were either limed or tilled.

Reference - never limed for liming analyses, never tilled for tilling analyses (West Amendment Plot with its reference plot was included in the reference plots, as it was never treated or tilled).

ANOVA = Analysis of Variance with Post-hoc Tukey's HSD test used to obtain 95% confidence intervals on least squares means

Figures 16 and 17 show bar graphs of the least square means in this table (and their differences). Least square means are the average of the average values of the ANOVA categories by plot type and sampling period within the effect level of interest.

Cu = copper pCu = cupric iron activity

Table 9b

Interaction term of (Pre vs. Post-Tilling Period) and (Tilled Plot vs. Untilled Plot)	1	314	1.63	0.20

Notes:

[1] Log transformed means were used with standard errors and confidence intervals; means are back-transformed to original units.

BACI is a mixed model ANOVA with fixed factors of planned treatment of plot (reference vs. amendment plot) and time period (before and after treatment) and random factors of plot location and sampling period.

Bolded P values are significant at $P < 0.05$. *Italicized* P values are nearly significant ($P \leq 0.10$).

See Table 9a for means for each category of the ANOVA and 95 percent confidence intervals from the Tukey's HSD Post-hoc comparison test

Amendment - plots that were either limed or tilled.

Reference - never limed or tilled (West Amendment Plot with its reference plot was included in the reference plots, as it was never treated or tilled).

ANOVA = Analysis of Variance Cu = copper pCu = cupric ion activity SPLP = Synthetic Precipitation Leaching Procedure mg/kg = milligrams per kilogram

Table 10

Mixed Model ANOVA[1] Results of Amendment Plots Before and After Amendment Application - Soluble Copper, TOC, and C:N Ratio

Year 5 Amendment Study Monitoring Report
Freeport-McMoRan Chino Mines Company
Vanadium, New Mexico

Analyte	Mean Estimate Before Amendments[2]	Mean Estimate After Amendments	P-value
Comparison to one sampling event after application (6 months later)			
Soluble Copper [3]	0.10	0.91	**0.02**
TOC	1.09	1.43	0.14
C:N Ratio	18.16	20.38	0.32
Comparison to two sampling events after application (1.5 years later)			
TOC	1.09	1.47	**0.02**
C:N Ratio	17.84	13.07	**0.04**

Notes:

1 - No reference plots included because no data were available in the early years for reference plots (no BACI design). Amendments = lime and organic matter.

2 - Mean is average of average of plot type and sampling period, referred to as least square mean

3 -Soluble copper was log transformed in the tests; means shown are back-transformed to original units.

ANOVAs for TOC and C:N included 2006 data because these parameters were assumed to be unaffected by the white rain event.

ANOVA = Analysis of Variance
C:N = carbon:nitrogen ratio
Cu = copper
mg/L = milligrams per liter
SPLP = Synthetic Precipitation Leaching Procedure
TOC = total organic carbon

Bolded P values are significant at $P < 0.05$. *Italicized* are nearly significant ($P < 0.10$).

Degrees of freedom are 1,9 (numerator, denominator) for soluble copper, 1,14, for TOC/C:N for 6 months after, and 1,23 for 1.5 years after.

Table 11

Notes:

1 Amendment Study Method is average of eight 0-6" depth random samples in 104' x 104' square in 2012 and 2013. From 2010 to 2011, two samples were taken.

2 pH monitoring method is five composite samples in 50 m x 50 m square (taken at corners and center, shifted over each year).

pCu = cupric iron activity

Table 12b

North					
Percent Cover	25	Uncertain[4]	22	-3	Uncertain
Species Richness	3	Increased	-1	-4	Uncertain
Shannon Diversity	0.88	Increased	-0.21	-1.09	Uncertain
Evenness	0.32	Increased	-0.10	-0.42	Decreased
West (2 reference plots)					
Percent Cover	0, -11	Neither to Decreased	--	--	--
Species Richness	8, 6.5	Increased	--	--	--
Shannon Diversity	0.61, 0.31	Increased	--	--	--
Evenness	0.04, -0.04	Neither	--	--	--

Note:

1 - Year 2008 is March 2008, which is dormant season representing pre-white rain community that grew in growing season of fall 2007. Numbers in the second column are the absolute change between before white rain and last sampling year of 2013 in reference plots. However, effect of variabililty over time is missed in such comparisons and thus statistical analyses in Appendix 20a (one-sample *t* test) compared the post-white rain mean to pre-white rain estimates, and if not significant then direction of change is considered to be "neither", or if large change, "uncertain". The same process was used to evaluate change from treatments reported in the last column.

2 - Sample size is one (n=1) for each reference plot, and thus decision had to be based on professional judgment based on magnitude of difference at end of 5 years and variability (if mean significantly different in Appendix 20a) during the 4 post-effect years.

3 -Though P = 0.53 in Appendix 20a, the high variability is driven by low cover during spring season 2010 when the herbaceous plant material that had become abundant after tilling dies back; Excluding this spring season produces a significant increase in cover (P = 0.04).

4 - Though significant at P = 0.07 (Appendix B-20a), the low spring 2008 pre-white rain cover estimate occurs again in spring 2010 and during another fall period, falling within the range of variability, creating uncertainy as to whether it increased or not (see Figure 9a).

-- means not evaluated. The two control West plots were not treated with amendment or tilling and are evaluated only for white rain effects

Italics means within magnitude of range of change of two West control plots that were not treated, making this conclusion less certain.

Note:

1 - Year 2008 is March 2008, which is dormant season representing pre-white rain community that grew in growing season of fall 2007. Numbers in the second column are the absolute change between before white rain and last sampling year of 2013 in reference plots. However, effect of variabililty over time is missed in such comparisons and thus statistical analyses in Appendix 20a (one-sample *t* test) compared the post-white rain mean to pre-white rain estimates, and if not significant then direction of change is considered to be "neither", or if large change, "uncertain". The same process was used to evaluate change from treatments reported in the last column.

2 - Sample size is one (n=1) for each reference plot, and thus decision had to be based on professional judgment based on magnitude of difference at end of 5 years and variability (if mean significantly different in Appendix 20a) during the 4 post-effect years.

-- means not evaluated. West plots were not treated with amendment or tilling and are evaluated only for white rain effects

Italicized values mean within magnitude of range of change of two West control plots that were not treated, making this conclusion less certain.

Table 17
Weight of Evidence Table for Primary Metrics by Amendment Type and Plot Type

Year 5 Amendment Study Monitoring Report
Freeport-McMoRan Chino Mines Company
Vanadium, New Mexico

Amendment Approach and Plot Type	pCu increase?[1]				If pCu increased, did Cu concentration decrease in tissue?			If pCu increased, did richness increase?[2]		If pCu increased, did cover increase?[2]		Vegetation Establishment/Composition after 5 Years[2]	Method Recommended for Plot Type?
	Initially increase from technology or white rain?	Effect persistent?	Persistent Relative to Reference?	Meet pre-FS RAC?	Initially decrease? Decrease to near background level for herbaceous species (≤13 mg/kg)?	Effect persistent?	Persistent relative to Reference?	Initially increase relative to reference (if reference available)?	Effect persistent (if not initially effective, then effective later)?	Initially increase (relative to reference if available)?	Effect persistent (if not initially effective, then effective later)?	All Short and Long-term (5-year) Criteria Likely Met with Method? Rangeland Grasses Improve?	
White Rain (initial) and Subsequent Natural Attenuation (persistence for 5 years)													
Poor Rangeland (East)	Yes	Yes (inc.)	--	No	Yes/Yes	Yes	--	Yes	Yes	No	No	No criteria; beardgrass, silverleaf nightshade, and carelessweed newly established in small amounts	**NA**
Fair Rangeland (North)	Yes	Yes	--	Yes	Yes/Yes	Yes	--	Yes	No (uncertain)	Yes (but uncertain)	No (inconsistent)	No criteria; silverleaf nightshade and carelessweed newly established in small amounts	**NA**
Steep Slope, Fair Rangeland (Northeast)	Yes (smaller effect)	Yes	--	No	Yes/No	Yes	--	Yes	Yes	No	No	No criteria; silverleaf nightshade, vine mesquite, tobosa, and carelessweed newly established in small amounts	**NA**
West (control)	Yes	No (but still high)	--	Yes (even before white rain)	Yes/Yes	Yes	--	Yes	Yes	No	No	No criteria; carelessweed in high amount and some other forbs and grasses established in small amounts (may have been present before)	**NA**
Till to 8" depth (to potentially reduce soil Cu and increase pCu)													
Poor Rangeland (East)	No	--	--	--	--	--	--	--	--	--	--	Yes, except shrub density, shrub richness need more time, and no cool season grasses (not expected in future); also too many potentially toxic annuals. Gained perennial grasses (possibly from decompacting soil).	**No** (not to only 8", deeper possibly)
Fair Rangeland (North)	No	--	--	--	--	--	--	--	--	--	--	Yes, except not quite yet for shrub density, shrub richness, and no cool season grasses (not expected in future); also, too many potentially toxic annuals and loss of grass cover (tilling removed grasses, replaced with annual forbs). Set back to earlier stage of succession.	**No**
Lime added (at 1.3 t/ac) to increase pH on plots already limed with white rain (which would further increase pCu beyond white rain effect)													
Steep Slope, Fair Rangeland (Northeast)	No	--	--	No	No	--	No	No	--	--	--	Yes, except no cool season grasses; also loss of grass cover (possibly from disturbance or TOC in organic matter because liming from white rain alone did not decrease grasses)	**No**
Tilling and Lime added													
Poor Rangeland (East)	Not significant (P = 0.2) but low power so uncertain	If increased beyond white rain (uncertain), Yes	No	Yes	Yes/Yes (might be from white rain only)	Yes (might be only from white rain)	Yes (might be only from white rain)	No (because reference inc.)	Yes, but uncertain because small effect and may not be due to pCu change	Yes (uncertain if due to pCu change)	Yes (uncertain if due to pCu change)	Yes, except shrub density and shrub richness need more time; no cool season grasses; also too many potentially toxic annuals. Gained perennial grass (possibly from tilling decompacting soil because of CCA results and lime in white rain alone did not increase grasses).	**Yes**, only if (1) no steady improvement in pCu naturally, and (2) degradation is due to copper toxicity, not just overgrazing.Most of the improvement was from decompaction and only small change from white rain increasing pCu.
Fair Rangeland (North)	Not significant (P = 0.2) but low power so uncertain	If increased beyond white rain (uncertain), Yes	If increased beyond white rain (uncertain), Yes	Yes	Yes /Yes (might be from white rain only)	Yes (might be only from white rain)	Yes (might be only from white rain)	No	No	No	--	Yes, except not quite yet for shrub density, shrub richness; no cool season grasses; also, too many potentially toxic annuals and loss of grass cover (and grasses not lost by liming from white rain alone so may be from tilling and organic matter). Set back to earlier stage of succession.	**No**
Organic Matter Effective?[3]													
Steep Slope, Fair Rangeland (Northeast)	No	No	--	--	No	--	--	--	--	--	--	Vegetation established, except no cool season grasses; organic matter may increase annual forbs somewhat and their toxicity; may decrease perennial grasses, facilitating high-nutrient-loving annual weeds	**No**

Notes:

1 - Conclusions are estimates based on weight of evidence for plots evaluated with their pH and pCu levels and are also supported by change in supporting metrics such as pH (increased from white rain alone and on amended and tilled plots but not on limed-only plot) and ABA results (found not to be acid-generating); calculated pCu was verified by measured pCu. Met pH criteria of ≥ 5.5. Soluble copper and total copper did not significantly decrease from white rain or any remedial technology.

2 - More qualitative and uncertain as to cause. May be affected by pCu, weather, TOC (TOC increased from organic matter and natural attenuation, meeting target of 1%) , or C:N (decreased from natural attenuation and organic matter, meeting target of below 15:1), and supplemental nutrient data (nitrites/nitrates increased, especially on East and North plots). Note that C:N was lower than minimum 8:1 target on poor rangeland plot at 7.5:1 (too much organic matter at 48 t/ac). If pCu did not increase with a corresponding decrease in tissue Cu, could assume any changes in cover and richness not caused by the remedial technology, but note that pCu results for tilled and amended plots are highly uncertain due to low power of tests.

3 - Organic matter effectiveness can not be evaluated for the poor rangland and fair rangeland areas on relatively flat ground (North and East) because not separated from lime or tilling effects. Lime and organic matter were ineffective at changing pCu on Northeast plot, so organic matter assumed ineffective.

-- = not applicable

ABA = acid-base accounting

C:N = carbon:nitrogen ratio

mg/kg = milligrams per kilogram

NA = not available

Cu = copper

pCu = cupric iron activity

pre-FS RAC = pre-Feasibility Study Remedial Action Criteria

TOC = total organic carbon

inc. = increased over five years

Table 18
Evaluation of Weight of Evidence for Effectiveness of Three Treatments when Applied Separately

Year 5 Amendment Study Monitoring Report
Freeport-McMoRan Chino Mines Company
Vanadium, New Mexico

Treatment effect alone[1]	Rangeland condition, soil category[2]	Increase?								
		pH	pCu	reduction of copper uptake in plants	cover	richness	grass cover	successional stage	Notes on Effect	Recommended as a remedy alone?
Lime	poor, flat rocky (East)	yes	yes	yes	No	Yes	Minor[3]	Minor	white rain report, this report, phytotoxicity & community report. Sitewide ERA	
	fair, flat granular (North)	yes	yes	yes	Minor	Yes	Minor[3]	Minor	white rain report, this report, phytotoxicity & community report. Sitewide ERA	No, because it did not increase total cover, which is needed to improve habitat for wildlife and livestock.
	fair, slope (Northeast)	yes	yes	yes	No	Yes	Minor[3]	Minor	white rain report, this report, phytotoxicity & community report. Sitewide ERA	No, because it did not increase total cover, which is needed to improve habitat for wildlife and livestock.
Tilling	poor, flat rocky (East)	unknown	unknown	unknown	Yes	Yes	Yes	Yes	Anecdotal observations of haul road in early years, photos in later years, decompaction is key, but mixing surface and subsurface may increase pCu	Yes, haul road tilling was effective in improving habitat for wildlife and livestock
	fair, flat granular (North)	unknown	unknown	unknown	No	No	No	No	Reversed successional stage by increasing annuals, decreasing grass cover	No, more harm than good. Decompaction of granular soil not needed, and disturbance will set back succession too long
	fair, slope (Northeast)	--	--	--		--	--	--	Slope terrain is too rough and can not be tilled	No, more harm than good, plus not feasible to till
Organic matter	poor, flat rocky (East)	No[4]	No	No	unknown	No	No	No	Lime and tilling caused an increase in richness, unlikely organic matter increased it more based on literature. Unless organic matter extremely low (not the case in test plots), unlikely will increase cover. Tilling without organic matter produced a beneficial outcome of high grass diversity and abundance. Organic matter may have slowed succession to desired outcome.	No, generally not effective in semi-arid soils and possibly detrimental.
	fair, flat granular (North)	No[4]	No	No	No	No	No	No	Organic matter, lime and tilling reversed succession and decreased evenness and grasses. Though uncertain, organic matter may facilitate weed invasion and slow down succession and reduce diversity.	No, generally not effective in semi-arid soils and possibly detrimental.
	fair, slope (Northeast)	No[4]	No	No	unknown	unknown	No	No	Driving on plot and spraying reversed succession; no pH improvement or reduced pCu uptake from organics or lime, possibly increased soluble copper. Though uncertain, organic matter may facilitate weed invasion and slow down succession and reduce diversity.	No, generally not effective in semi-arid soils and possibly detrimental.

1- Based on white rain effects for lime (equivalent to light liquid spray), haul road effects for tilling or ripping (to 12 to 18 inches), and comparison of this study's combination of effects for organic matter and to literature.

2 - Bedrock not shown nor tested in this study, but showed no relationship with pCu in cover, though observed with richness. Bedrock runoff is high as on slope soils and remedies unlikely to be effective.

3 - Recorded as minor if uncertain or observed as minor (Table 16).

4 - Lime and organic matter combined (with no tilling) did not significantly change pH, so organic matter alone was assumed not to change pH (Table 9)

Table 19a
Before-After-Control-Impact (BACI) Means and Standard Errors - Copper, pCu, and Soluble Copper Without Less-Collocated plots

Year 5 Amendment Study Monitoring Report
Freeport-McMoRan Chino Mines Company
Vanadium, New Mexico

Analyte by BACI Level	Mean Estimate[1]	Standard Error	95% Confidence Interval	
			Lower	Upper

pre Reference	0.14	2.56	0.02	0.89
post Reference	0.72	1.38	0.38	1.37

Notes:

1- average of the average of categories (by plot type and sampling period), called least square mean. Post-treatment mean is based on all 5 years post-treatment.

2 - Log transformed means (and 5:1 dilution) were used with standard errors and confidence intervals; means are back-transformed to original units.

BACI is a mixed model ANOVA with fixed factors of planned treatment of plot (reference vs. amendment plot) and time period (before and after treatment) and random factors of plot location and sampling period.

Excludes white rain effect (no 2006 data)
till - plot that either will be or has been tilled (North and East Amendment plots)
Amendment - plots that were either limed or tilled.
Reference = northeast amendment plot

ANOVA = Analysis of Variance with Post-hoc Tukey's HSD test used to obtain 95% confidence intervals on least squares means

Least square means are the average of the average values of the ANOVA categories by plot type and sampling period within the effect level of interest.

Cu = copper pCu = cupric iron activity

Table19b
Before-After-Control-Impact (BACI) Mixed Model ANOVA Test Results - Copper, pCu and Soluble Copper Without Less-Collocated plots

Year 5 Amendment Study Monitoring Report
Freeport-McMoRan Chino Mines Company
Vanadium, New Mexico

Effect Level	Numerator df	Denominator df	F-Ratio	P-Value
Cu in mg/kg (till = add tilling)				
Pre- vs. Post-Tilling Period	1	9	2.56	0.14
Tilled vs. Untilled Plot	1	137	13.82	**0.0003**
Interaction term of (Pre vs. Post-Tilling Period) and (Tilled Plot vs. Untilled Plot)	1	137	0.20	0.65
pCu (till = add tilling)

Tilled vs. Untilled Plot	1	137	5.43	**0.02**
Interaction term of (Pre vs. Post-Tilling Period) and (Tilled Plot vs. Untilled Plot)	1	137	1.79	0.18
Soluble Copper by SPLP (till = add tilling)				
Pre- vs. Post-Tilling Period	1	5	3.16	0.14
Tilled vs. Untilled Plot	1	60	2.52	0.12
Interaction term of (Pre vs. Post-Tilling Period) and (Tilled Plot vs. Untilled Plot)	1	60	0.54	0.47

Notes:

BACI is a mixed model ANOVA with fixed factors of planned treatment of plot (reference vs. amendment plot) and time period (before and after treatment) and random factors of plot location and sampling period.

Bolded P values are significant at $P < 0.05$. *Italicized* P values are nearly significant ($P \leq 0.10$).

See Table 9a for means for each category of the ANOVA and 95 percent confidence intervals from the Tukey's HSD Post-hoc comparison test

Amendment - plots that were either limed or tilled.

Reference - never limed or tilled (West Amendment Plot with its reference plot was included in the reference plots, as it was never treated or tilled).

ANOVA = Analysis of Variance Cu = copper pCu = cupric ion activity mg/kg = milligrams per kilogram

Table 20
Mixed Model ANOVA[1] on Copper and pCu without Reference plots

Year 5 Amendment Study Monitoring Report
Freeport-McMoRan Chino Mines Company
Vanadium, New Mexico

Analyte by Level	Mean Estimate Before	Mean Estimate After	P-value
Cu in mg/kg (L= add lime and organic matter) - Comparison to one sampling event after application (6 months later)			
Mean copper	1,956	1,661	0.48
pCu in mg/kg (L= add lime and organic matter) - Comparison to one sampling event after application (6 months later)			
Mean pCu	4.14	4.24	0.91
Cu in mg/kg (L= add lime and organic matter) - Comparison to two sampling events after application (1.5 years later)			
Mean copper	1,956	1,690	0.45
pCu in mg/kg (L= add lime and organic matter) - Comparison to two sampling events after application (1.5 years later)			
Mean pCu	4.14	4.59	0.46
Cu in mg/kg (L= add lime and organic matter) - Comparison to all 5 years after application			
Mean copper	1,956	1,466	*0.064*
pCu in mg/kg (L= add lime and organic matter) - Comparison to all 5 years after application			
Mean pCu	4.14	5.07	*0.095*

Notes:

1- Plot is random factor and sampling period is random factor when analyzed for all years.

Excludes white rain effect (no 2006 data)

Amendment plots only were included, that were either limed or tilled. No reference plots were included.

ANOVA = Analysis of Variance with Post-hoc Tukey's HSD test used to obtain 95% confidence intervals on least squares means level of interest.

Cu = copper pCu = cupric iron activity

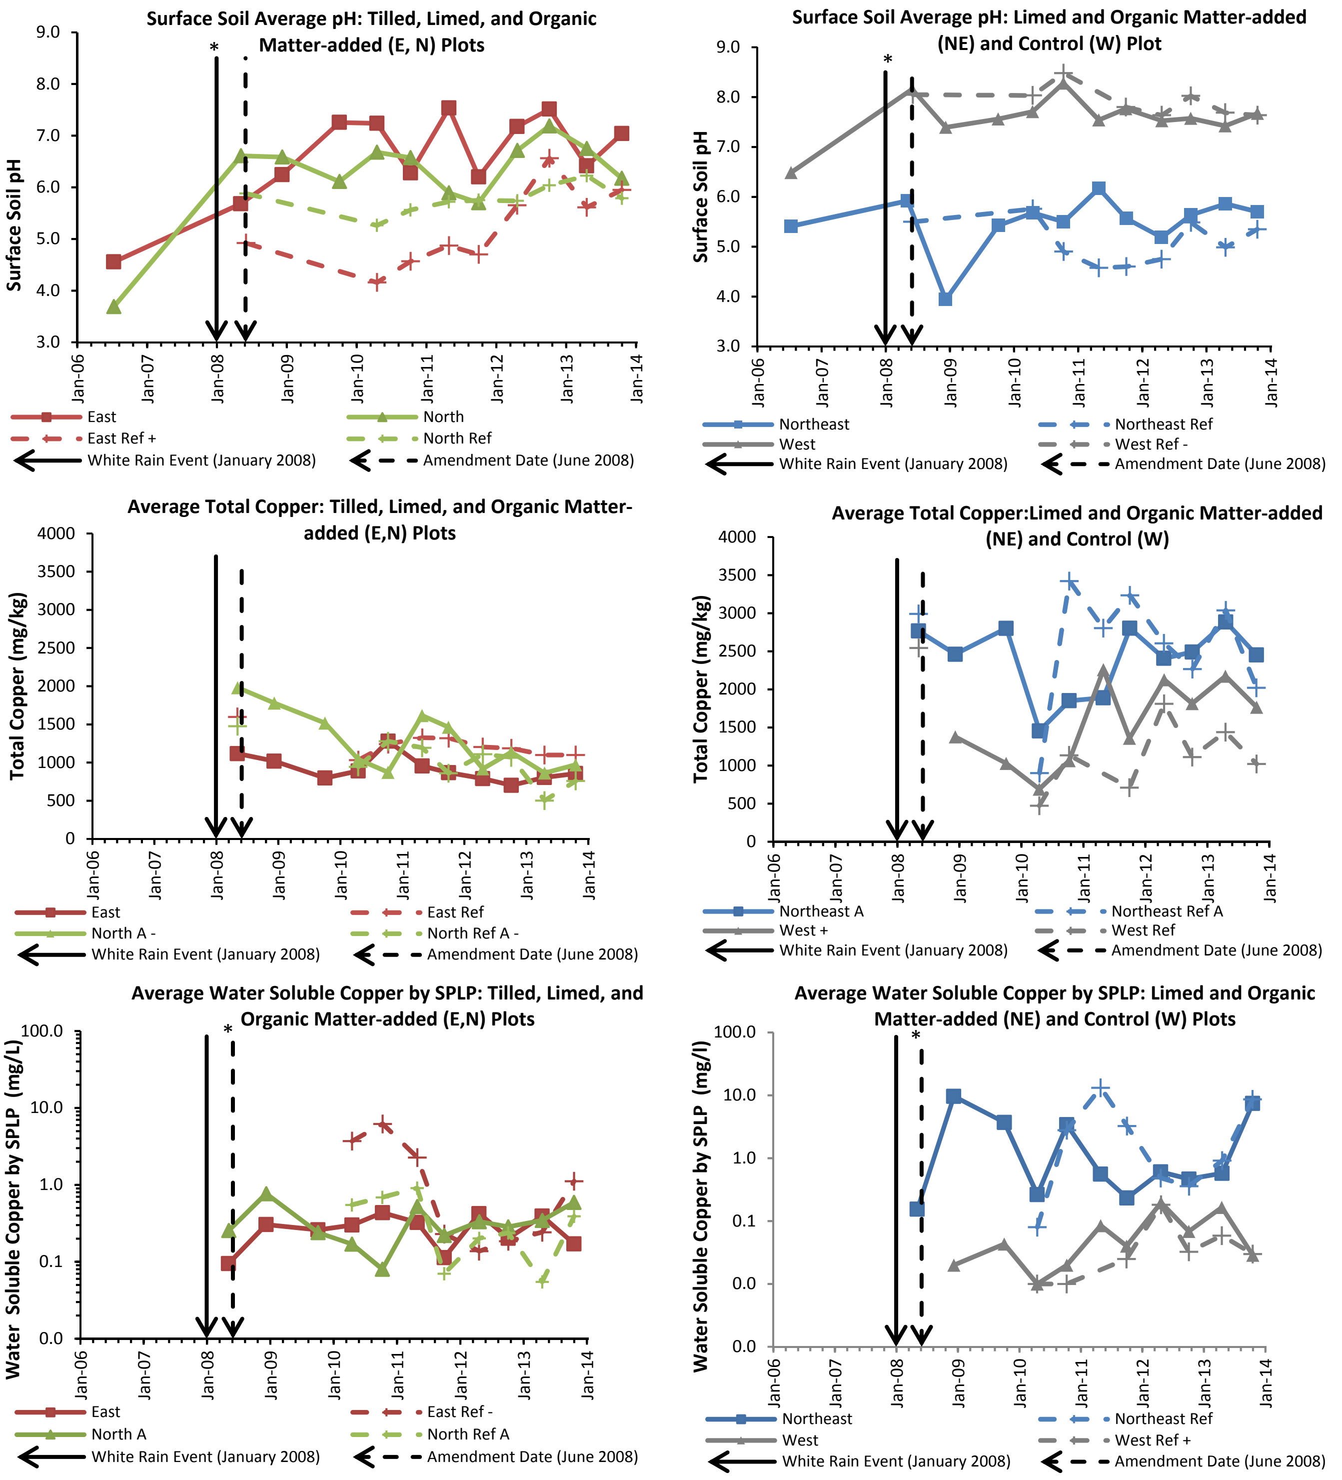
Schematic of Before-After-Control-Impact Study Design and Analysis

ARCADIS

FIGURE

3



Notes: The letter "A" next to a plot location in the figure legend indicates there is no significant difference between the paired amendment and reference plots. The symbol + or - next the legend plot location indicates trend post-amendment since December 2008 for amendment plots and since 2010 for reference plots is significantly increasing or decreasing, respectively (only events with 5:1 method tested statistically for SPLP, which are up to April 2011 plus October 2013). The asterisk above the white rain or amendment date arrow indicates the event caused a significant change based on BACI or ANOVA analysis. The significance of the amendment does not apply to the untreated west plots. Points not connected by a line are estimated.
The May/June 2008 mean pH was calculated using average of soil laboratory and field pH data. The field pH data are located in Appendix A-1.

YEAR 5 MONITORING REPORT – AMENDMENT STUDY PLOTS

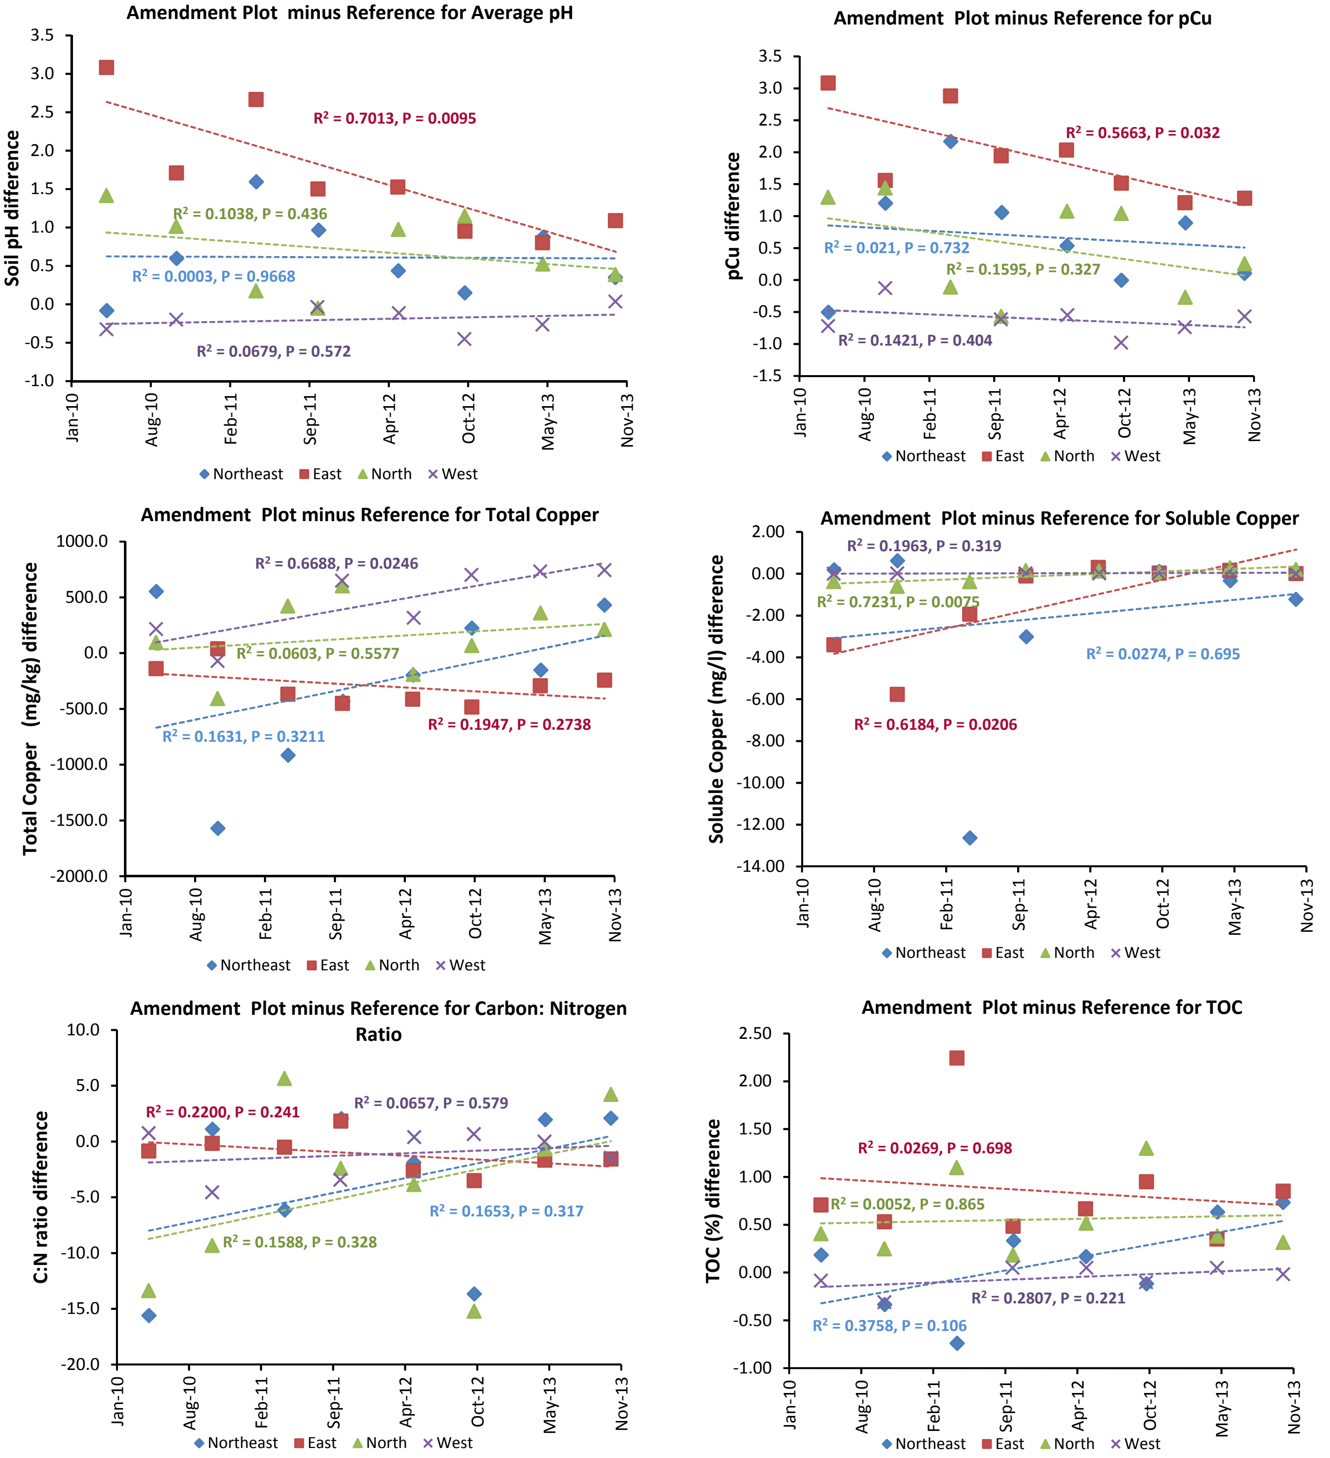
Surface Soil pCu, Total Organic Carbon (TOC), and Carbon: Nitrogen Ratio (C:N) in Amendment and Reference Plots over Time

ARCADIS

FIGURE

4b



Notes: If regression lines do not have significant slopes (different from 0) as indicated by P value > 0.05, then the initial amendment/tilling effect, if present, is not changing (appears persistent). However, if the regression line is near or approaching zero, then treatment in amendment plot may not have made a difference in the parameter if adjacent plots were similar before treatment. **Figures 4a** & **4b** or **Table 9** must be checked to interpret if reference areas started out with a large difference from amendment plots before the treatment , which may have diminished to near zero following the treatment (which could mean treatment was effective even if difference near zero). When the West plot (both plots are untreated) mean difference is not zero (e.g., for copper), it suggests high spatial variability in the parameter and not to rely on zero difference as meaning no effect. Difference data unavailable for 2008-09.

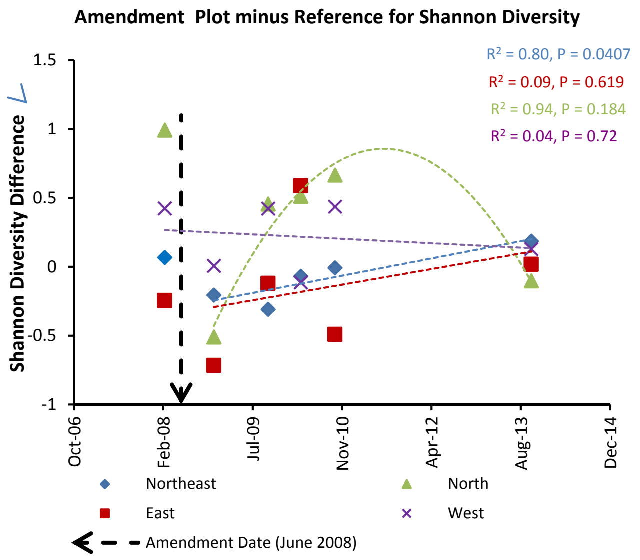
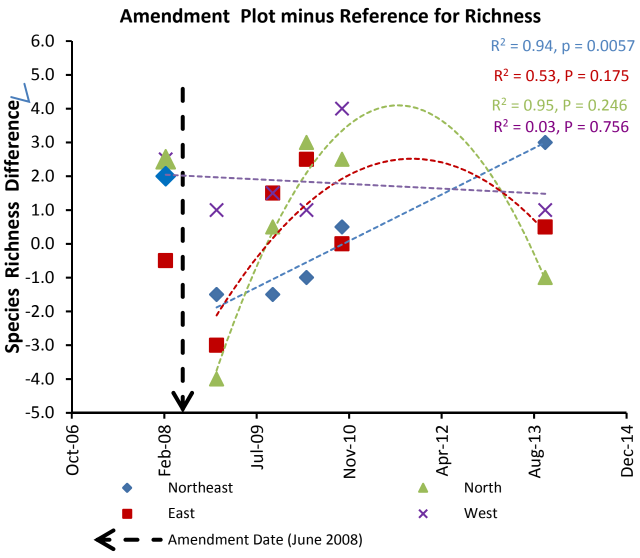
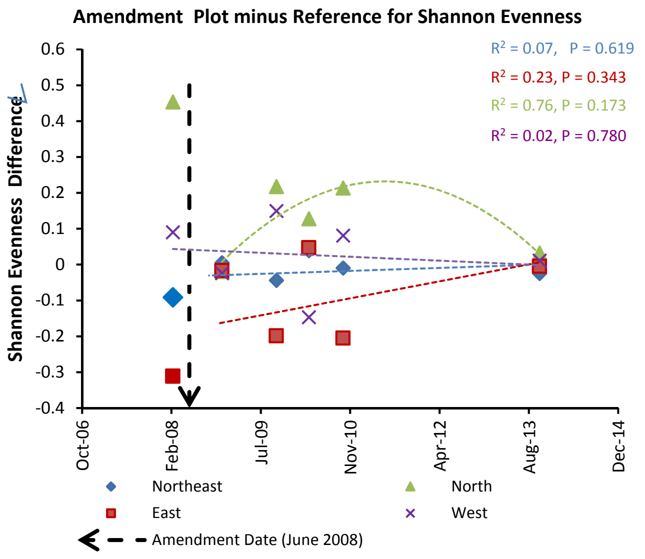
Amendment Plot minus Reference for Percent Cover



Amendment Plot minus Reference for Shannon Diversity



Amendment Plot minus Reference for Richness



Amendment Plot minus Reference for Shannon Evenness

Notes: If the difference changes by a noticeable amount from before amendment application to after (statistics not possible to test if significant), particularly by October 2013 after 5 years of succession, then the treatment may have had an effect. Linear and quadratic curves are fit to the data post-amendment only (not pre-amendment) to evaluate the trend post-amendment. If these regression lines do not have significant slopes (different from 0) as indicated by P value > 0.05, then the initial amendment/tilling effect, if present, is not changing (appears to be persistent). However, if it is or approaches the same difference value as before the amendment, the treatment appears not to be effective (unless it recovers to former difference and then surpasses it by October 2013).

Geology N/A

Check appropriate box in each category which best fits area being observed. Points may vary within ea

	VIGOR (10 points)	Desirable grasses, forbs and shrubs are vigorous, showing good health. These plants have goo color and produce abundant herbage.
7	(6 points)	Desirable grasses, forbs and shrubs have moderate vigor. They are medium size with fair color and produce moderate amounts of herbage. Some seed stalks and seed heads are present.
	(2 points)	Desirable grasses, forbs and shrubs have low vigor. They appear unhealthy with small size and poor color. Portions of clumps or entire plants are dead or dying. Seed stalks and seed heads are non-existent except in protected areas.
	SEEDLINGS (10 points)	There is seedling establishment of desirable grasses, forbs and shrubs. Seedlings are present in open spaces between plants and along edges of soil pedestals. Few seedlings of invader or undesirable plants are present.
7	(6 points)	Some seedlings of desirable grasses, forbs and shrubs may or may not be present in open spaces between plants. Some seedlings of invader or undesirable plant species may or may not be present.
	(2 points)	Few if any seedlings of desirable grasses, forbs and shrubs are being established. Seedlings of invader or undesirable plants are present in open spaces between plants.
	SURFACE LITTER (5 points)	Surface litter is accumulating in place.
4	(3 points)	Moderate movement of surface litter is apparent and deposited against obstacles.
	(1 point)	Very little surface litter is remaining.
	PEDESTALS (5 points)	There is little visual evidence of pedestalling. Those pedestals present are sloping or rounding and accumulating litter. Desirable forage grasses may be found along edges of pedestals.
4	(3 points)	There is moderate pedestalling with no visual evidence of healing or deterioration. Small rock and plant pedestals may be occurring in flow patterns.
	(1 point)	Most rocks and plants are pedestalled. Pedestals are sharpsided and eroding, often exposing grass roots.
	SURFACE CRUSTING (5 points)	There is little visual evidence of surface crusting.
4	(3 points)	There is moderate surface crusting with no visual evidence of healing or deterioration. (Note reason for cause)
	(1 point)	Severe surface crusting. (Note reason for cause)
	RILLS AND GULLIES (5 points)	Gullies (including rills) may be present in stable condition with moderate sloping or rounded sides. Perennials are establishing themselves on bottom and sides of channel.
4	(3 points)	Gullies are well developed with small amounts of active erosion. Some vegetation may be present.
	1 point)	Sharply incised V-shaped gullies cover most of the area with most of the gullies actively eroding. Gullies are mostly devoid of perennial plants. They have fresh cutting on the bottom.

Total: 30 Rating: 35-40 = Upward, 26-34 = Static, 16-25 = Downward

Field Notes:

AOC RANGELAND ECOLOGICAL CONDITION CRITERIA
(at a community level)

CRITERIA	GOOD	FAIR	POOR
	Phase 1:	**Soil Stability**	
A - horizon	[✓ Present and distribution unfragmented]	Present but fragmented distribution developing *or buried partly*	Absent, or present only in association prominent plants or with other obstruction *buried*
Pedestaling	No pedestaling of plants or rocks	[✓ Pedestals present, but on mature plants only, no roots exposed]	Most plants and rocks pedestaled; roots exposed
Rills and gullies	Absent, or with blunted and muted features	[✓ Small, embryonic, and not connected into a dendritic pattern]	Well defined, actively expanding, dendritic pattern established
Scouring or sheet erosion	No visible scouring or sheet erosion	[✓ Patches of bare soil or scours developing; moderate or slight erosion]	Bare areas and scours well developed and contiguous; erosion severe
Sedimentation or dunes	[✓ No visible soil deposition]	Soil accumulating around plants or small obstructions	Soil accumulating in large barren deposits or duns or behind large obstructions; obvious tailings present
	Phase 2:	**Plant Distribution**	
Distribution of plants (Sociability Class)	[✓ Most plants well distributed across site]	Most plant distribution becoming fragmented	Plants clumped, often in association with prominent individuals; large bare areas between clumps
Litter distribution and incorporation	[✓ Uniform across site]	Some litter present of litter becoming associated with prominent plants or other obstructions	Litter largely absent
Rooting structure	[✓ Community structure indicates rooting throughout the soil unit]	Community structure indicates absence of roots from portions of the soil unit	Community structure indicates rooting in only one portion of the soil unit
	Phase 3:	**Recovery Potential**	
Age-class distribution	Distribution reflects all species, seedlings generally present	[✓ Seedlings and young plants of some taxa missing]	Few to No seedlings, primarily old or deteriorating plants present
Plant vigor	Plants display normal growth form	[✓ Some plants developing abnormal growth form]	Most plants in abnormal growth form
Germination microsite	[✓ Microsites present and distributed across the site]	Developing crusts, soil movement, or other factors degrading microsites, developing crusts are fragile	Soil movement or crusting sufficient to inhibit most germination and seedling establishment

QA Check
date: 10·27·97
init: AR

Check appropriate box in each category which best fits area being observed. Points may vary within eac

	VIGOR (10 points)	Desirable grasses, forbs and shrubs are vigorous, showing good health. These plants have good color and produce abundant herbage.
8	(6 points)	Desirable grasses, forbs and shrubs have moderate vigor. They are medium size with fair color and produce moderate amounts of herbage. Some seed stalks and seed heads are present.
	(2 points)	Desirable grasses, forbs and shrubs have low vigor. They appear unhealthy with small size and poor color. Portions of clumps or entire plants are dead or dying. Seed stalks and seed heads are non-existent except in protected areas.
	SEEDLINGS (10 points)	There is seedling establishment of desirable grasses, forbs and shrubs. Seedlings are present in open spaces between plants and along edges of soil pedestals. Few seedlings of invader or undesirable plants are present.
8	(6 points)	Some seedlings of desirable grasses, forbs and shrubs may or may not be present in open spaces between plants. Some seedlings of invader or undesirable plant species may or may not be present.
	(2 points)	Few if any seedlings of desirable grasses, forbs and shrubs are being established. Seedlings of invader or undesirable plants are present in open spaces between plants.
	SURFACE LITTER (5 points)	Surface litter is accumulating in place.
3	(3 points)	Moderate movement of surface litter is apparent and deposited against obstacles.
	(1 point)	Very little surface litter is remaining.
	PEDESTALS (5 points)	There is little visual evidence of pedestalling. Those pedestals present are sloping or rounding and accumulating litter. Desirable forage grasses may be found along edges of pedestals.
3	(3 points)	There is moderate pedestalling with no visual evidence of healing or deterioration. Small rock and plant pedestals may be occurring in flow patterns.
	(1 point)	Most rocks and plants are pedestalled. Pedestals are sharpsided and eroding, often exposing grass roots.
	SURFACE CRUSTING (5 points)	There is little visual evidence of surface crusting.
3	(3 points)	There is moderate surface crusting with no visual evidence of healing or deterioration. (Note reason for cause) not enough cover
	(1 point)	Severe surface crusting. (Note reason for cause)
	RILLS AND GULLIES (5 points)	Gullies (including rills) may be present in stable condition with moderate sloping or rounded sides. Perennials are establishing themselves on bottom and sides of channel.
4	(3 points)	Gullies are well developed with small amounts of active erosion. Some vegetation may be present.
	1 point)	Sharply incised V-shaped gullies cover most of the area with most of the gullies actively eroding. Gullies are mostly devoid of perennial plants. They have fresh cutting on the bottom.

AOC RANGELAND ECOLOGICAL CONDITION CRITERIA
(at a community level)

HW-155/160

CRITERIA	GOOD	FAIR	POOR
	Phase 1:	**Soil Stability**	
A - horizon	Present and distribution unfragmented	[✓ Present but fragmented distribution developing *or buried partly*]	Absent, or present only in association prominent plants or with other obstruction *buried*
Pedestaling	No pedestaling of plants or rocks	[✓ Pedestals present, but on mature plants only, no roots exposed]	Most plants and rocks pedestaled; roots exposed
Rills and gullies	Absent, or with blunted and muted features	[✓ Small, embryonic, and not connected into a dendritic pattern]	Well defined, actively expanding, dendritic pattern established
Scouring or sheet erosion	No visible scouring or sheet erosion	[✓ Patches of bare soil or scours developing; moderate or slight erosion]	Bare areas and scours well developed and contiguous; erosion severe
Sedimentation or dunes	[✓ No visible soil deposition]	Soil accumulating around plants or small obstructions	Soil accumulating in large barren deposits or duns or behind large obstructions; obvious tailings present
	Phase 2:	**Plant Distribution**	
Distribution of plants (Sociability Class)	Most plants well distributed across site	[✓ Most plant distribution becoming fragmented]	Plants clumped, often in association with prominent individuals; large bare areas between clumps
Litter distribution and incorporation	Uniform across site	[✓ Some litter present of litter becoming associated with prominent plants or other obstructions]	Litter largely absent
Rooting structure	Community structure indicates rooting throughout the soil unit	[✓ Community structure indicates absence of roots from portions of the soil unit]	Community structure indicates rooting in only one portion of the soil unit
	Phase 3:	**Recovery Potential**	
Age-class distribution	Distribution reflects all species, seedlings generally present	[✓ Seedlings and young plants of some taxa missing]	Few to No seedlings, primarily old or deteriorating plants present
Plant vigor	[✓ Plants display normal growth form]	Some plants developing abnormal growth form	Most plants in abnormal growth form
Germination microsite	[✓ Microsites present and distributed across the site]	Developing crusts, soil movement, or other factors degrading microsites, developing crusts are fragile	Soil movement or crusting sufficient to inhibit most germination and seedling establishment

Appendix B-1

Standard Operating Procedure for Foliage Sampling for Copper at Four Amendment Areas

Foliage was sampled in October 2013 at all four amendment pilot study areas, as well as at associated reference areas, to evaluate concentrations of copper in above ground biomass. October 2013 reflects five years after completion of construction activities associated with the Smelter/Tailing Soils Investigation Unit Amendment Study plots, and the conclusion of monitoring activities consistent with the approved *Administrative Order on Consent – Amendment Study Work Plan, Smelter/Tailing Soil Investigation Unit* (ARCADIS 2008).

Species selection for copper concentration analysis was performed at the beginning of the pilot study on March 20, 2008. The plant species are summarized below.

West amendment plot: purple loco (*Oxytropis lambertii),* blue grama *(Bouteloua gracilis),* Arizona three-awn *(Aristida arizonica),* snakeweed *(Gutierrexia sarothrae),* sideoats grama *(Bouteloua curtipendula)*
North amendment plot: sideoats grama (*Bouteloua curtipendula),* vine mesquite *(Panicum obtusum),* Arizona three-awn *(Aristida arizonica)*
Northeast amendment plot: sideoats grama (*Bouteloua curtipendula*)*,* blue grama *(Boutelous gracilis)*
East amendment plot: snakeweed (*Gutierrexia sarothrae), Aster sp.,* vine mesquite (*Panicum obtusum)*

However, not all species could be included at the end of the five-year pilot study in 2013 due to decreases in abundance of some of these species within the amendment plots over time (i.e., *Gutierrexia sarothrae*). When such changes were required, ARCADIS attempted to best reflect (1) dominant perennial grass, forb, or shrub species within a plot, and (2) consistency of species across the four amendment pilot study areas where possible. An inventory of samples collected on October 8 to 10, 2013 to be analyzed is included in **Table 8**, and summarized below.

West amendment plot: sideoats grama (*Bouteloua curtifpendula),* honey mesquite *(Prosopis grandulosa),* red three-awn *(Aristida purpurea)*
North amendment plot: honey mesquite (*Prosopis grandulosa),* vine mesquite *(Panicum obtusum),* sideoats grama *(Bouteloua curtifpendula)*
Northeast amendment plot: sideoats grama (*Bouteloua curtifpendula),* honey mesquite *(Prosopis glandulosa),* vine mesquite *(Panicum obtusum)*
East amendment plot: golden crownbeard (*Verbesina encelioides),* honey mesquite *(Prosopis glandulosa),* green bristlegrass *(Setaria viridis),* sideoats grama *(Bouteloua curtifpendula),* vine mesquite *(Panicum obtusum)*

Vegetative material was collected for each selected species (**Table 8**) from random individuals across each amendment area. The sampler randomly traversed each amendment area, collecting vegetated material from multiple individuals. For smaller herbaceous species, entire plants were harvested by cutting vegetative material just above the soil surface including seeds and fruits. For shrub species, leaves, petioles, and fruit material were collected. This approach followed the same approach used in 2008 of combining all plant material, whether foliage or seeds. No woody material was sampled. All samples were collected in brown paper lunch bags to keep samples dry and prevent molding. Each bag was labeled with species name, sampling location, name of sampler, and date. Consistent with laboratory requirements, approximately half of a standard size brown paper lunch bag was filled with vegetative material. For each species, two paper bags were filled for each amendment area as well as the associated reference areas.

Two samples were collected for each species. One sample was cleaned to remove soil and dust. The other sample was compared to previous survey results because sample cleaning was not performed at the beginning of the 5-year study.

Cleaning was performed by filling three stainless steel bowls with distilled water. Vegetative material was placed in the first bowl and effectively stirred, allowing dust and dirt to fall off. This was done three times in each of the bowls to facilitate an effective cleaning of the collected vegetative material. Following washing, each sample was patted dry with paper towel and allowed to dry overnight. Once the samples were dry, the materials were placed in new brown paper lunch bags and a desiccant package added to each. All samples were sent overnight express to the laboratory for analysis.

Cleaning activities were performed on one sample to address the concern of dust and/or soil material biasing the analysis. While previous analyses associated with the risk assessment were focused on any copper that may accumulate through the food chain, the focus of this analysis is on only the uptake of copper in above-ground biomass to evaluate the effectiveness of the amendments on the plant community. Given the limited size of each amendment plot, dust collected on each plant likely did not originate within only the amendment plot area. Therefore, these cleaned samples will provide a more accurate evaluation of copper taken up and stored in above-ground vegetative material. In addition, the data collected in 2013 will provide comparisons within each amendment area to samples collected in the associated reference areas (no reference data were collected in March 2008).

Appendix B-2

Appendix B-3

Quality of Vegetation Re-establishment

This appendix evaluates if the vegetation re-establishment has produced a community similar to the one present prior to disturbance or is on an expected trajectory toward such a community. In contrast, the main text of the report evaluates if the reduction in pCu improved the plant community for use as wildlife or rangeland habitat.

Arcadis assessed the success of vegetation re-establishment following disturbance caused by the remedial actions by examining the (1) relative proportion of life forms (annual/perennial, grass/forb/shrub), (2) vegetation cover, (3) species diversity measures, and (4) native species composition in amendment versus reference plots. These metrics were measured in both the circular subplots established for this study (ARCADIS 2008a and ARCADIS 2011b) and in Closure/Closeout Plan (CCP) quadrats (Daniel B. Stephens & Associates, Inc. 1999 and Chino 2007). Results obtained from the CCP quadrats were compared to criteria as discussed in the text. This appendix provides more details on trends in these characteristics and relates the results to literature on vegetation successional processes.

Tables and figures cited throughout the text are associated with the main report or **Appendix B** as noted.

1. Life Forms Established by End of 5-year Sampling Period in 2013

West Amendment Plot. In fall 2013, five years after amendments and/or tilling, the West amendment plot contained relatively even proportions of annual and perennial forbs, perennial grasses, and shrubs (**Appendix B-10**). Heterogeneity was high in this plot in fall 2013 as compared to earlier sampling periods (e.g., fall 2010) when perennial grasses dominated and shrubs and annual species were sparse on the sampling transects. The West plot is a control plot because it is untreated. However, the West plot does not characterize conditions targeted after re-establishment for the amended East, Northeast, and North plots because it is in the mixed grama herbaceous alliance (Newfields 2005), a different, more grass-dominated vegetation alliance than the mesquite/grama alliance of the other three plots. Nonetheless, this control plot shows vegetation shifts commonly occur naturally over time.

Northeast Amendment Plot. The untilled Northeast amendment plot represents the steeper slopes that are in the mesquite-and grama-dominated vegetation alliance (called mesquite/grama alliance, Newfields 2005), an alliance that is dominated by mesquite. In 2013, this plot was mostly dominated by perennial forbs and shrubs, life forms that were common in the plot prior to amendments (**Appendix B-10**). Notably, perennial grasses were more common prior to amendment application than in later sampling periods up to 2013 (**Figure 10).** Annual forbs were more common in 2010 but decreased by 2013 (**Appendix B-10**, **Figure 8**). These results suggest that re-establishment of the original proportions of the life forms, particularly grasses, is still in progress.

North and East Amendment Plots. Both the tilled North and East amendment plots are also in the mesquite/grama alliance but showed the opposite pattern in annual forbs from the Northeast amendment plot; these plots were dominated by annual forbs (early successional species), which have been steadily increasing over time (**Appendix B-10, Figure 8**). The trends in species composition in the North and East amendment plots were expected, given the effects of clearing and tilling that occurred in conjunction with the amendment application. The application of manure on the tilled plots can distribute seeds carried in the manure, and may have contributed to the large quantity of two highly aggressive species, carelessweed (*Amaranthus palmeri*) and golden crownbeard (*Verbesina encelioides*), which are potentially toxic to livestock (Kingsbury 1964). Current trends indicate that it may be decades before the communities on the tilled plots reach a more stable composition of perennial species, which is not unexpected (Romme et al. 2003, Daniel B. Stephens & Associates, Inc. 1999, and Chino 2007). Not applying manure may reduce the percent of annuals, as seen on the Golf Course remediation area (ARCADIS 2014a) that used hydro mulch seeding instead of manure, where percentage of cover in annual species after five years was reduced to 28 percent from 46 to 59 percent in the first year.

2. Vegetation Cover

East Plot. The criteria of increasing vegetative cover and reducing bare soil was met in the first year after treatment for the East amendment plot (**Figure 9a, Appendix B-13**). The high cover levels of non-natives such as Russian thistle (*Salsola tragus*) and other species that invaded the site helped to achieve this goal (**Table 15**). Though vegetative cover decreased the following year due to decrease in non-native cover the levels of cover then increased to very high levels by 2013 (**Figure 9a and Figure 12**) due in part to the establishment of native species (**Table 15**). Some of the variability over time is due to the artifact of the season sampled. Spring (sampled in 2008 and 2010) has lower cover compared to fall in this region (**Table 9a**). **Figure 11** displays the change in vegetative cover between amendment and reference plots over time, which reduces this confounding seasonal effect. The "difference in percent cover" in **Figure 11** for cover on the East plot shows a horizontal regression line fit to the data, indicating that the cover in the East amendment plot did not significantly change over time after amendment/tilling relative to the reference plot (both plots increased in cover post-amendment); however, overall cover was higher on the amended East plot after amendments were applied.

North and Northeast Plot. In contrast to the East plot, the North amendment plot cover decreased relative to its reference plot but eventually recovered. Of the four amendment plots, bare soil was highest in the North plot and lowest in the other tilled plot (East) in 2013, but vegetative cover was almost the same in the North plot as in the untreated West plot in 2013 (**Appendix B-5**). Unlike the North plot, the Northeast plot showed positive increases in cover relative to the reference plot over time ($P = 0.200$ for Northeast plot, see **Figure 11**). Note that none of these qualitative changes in "differences in means" for cover in **Figure 11** for any of the plots were statistically significant ($P \geq 0.20$) trends over time post-amendment. Sample size was small ($n = 6$) and limited the ability to detect significant differences.

Using CCP sampling methods, the vegetation cover in the amendment plots ranged from 58 to 79 percent in fall 2013 (**Table 14**). These cover estimates easily exceed the cover requirement of 38 percent set by the CCP guidelines (70 percent of South Tailings Reference Area cover, Daniel B. Stephens & Associates, Inc. 1999 and Chino 2007). Additional data regarding the relative cover of vegetation and bare soil using the CCP quadrats and circular subplots are provided in **Appendix B-11** and **Appendix B-13,** respectively.

3. Species Diversity

A diversity of species successfully colonized the tilled plots, thus meeting the CCP species diversity criterion. The diversity in the limed but untilled Northeast plot was also sustained. All plots met the minimum

CCP criterion of eight species for richness, with 9 to 11 species in the tilled plots and 14 species in the untilled Northeast plot (**Table 14**).

East Plot. The East amendment plot started with very low diversity and species richness before amendment (**Appendix B-13)**, which quickly improved less than a year after the clearing and tilling (**Figure 9a** and **Figure 9b**). Amendment and tilling initially improved the community; richness, evenness, and Shannon diversity of the East plot plant community, however, it did not significantly change relative to its reference plot (trend lines fit to data are not significant at P = 0.619 in **Figure 11**). Sample size was small (n = 6) and variability high from including different seasons in the trend, which limited the ability to detect significant differences.

North Plot. In contrast to the East amendment plot, the North amendment plot initially decreased in diversity after amendment (**Figure 9a, Figure 9b**) and in both diversity and richness relative to the reference plot (**Figure 11**), but then recovered. After amendment and tilling and relative to its reference plot, the three diversity measures did not significantly change over time (**Figure 11**).

Although not statistically significant, the quadratic (hump-shaped) trends in the tilled plots in **Figure 11** fit ecologists' "intermediate disturbance hypothesis" that states highest richness or diversity will be at intermediate levels of disturbance (Molles 2005). Richness and diversity values are low after heavy disturbance (tilled) when only colonizing species thrive, and values are low with low disturbance after enough time has passed that the most competitive species take over and dominate. At intermediate levels of disturbance, there are multiple colonizers and competitive species that increase overall diversity. Following this pattern, the disturbance of the tilled plots resulted in a level of richness improvement that peaked at levels above and beyond the reference plot levels in late 2010 (**Figure 11**) and decreased again by 2013.

Northeast Plot. The Northeast plot was limed and organic matter spread on top of the plants. The data suggest that these activities initially decreased diversity and richness, but both vegetation parameters steadily and significantly recovered relative to the reference plot (**Figure 11**). In contrast, evenness on this plot started out low and improved with the treatment relative to the reference plot, though the trend was not significant (**Figure 11**).

West Plot. As expected, the West amendment plot, as the control, showed no change over time in diversity, richness, or evenness relative to its reference plot. This was shown by the relatively flat lines with mean difference near zero in **Figure 11**, except richness mean difference was higher (near 2) on the amendment plot, indicating some spatial variability in richness between the two untreated plots.

Overall, the assessment of the three diversity measures indicates successful establishment of a diverse vegetation community on the amended plots.

4. Native species and Changes in Species Composition

The criterion of re-establishment of a predominantly native community was also met. Vegetation colonization and succession on the plots that were cleared and tilled followed a typical pattern that included an initial influx of non-native species. By 2013 these non-natives were reduced to a low level of less than 5 percent (**Figure 12**; this analysis assumes *Setaria* sp. on the East amendment plot is a native, but it may be the non-native *Setaria viridis.* If so, non-natives represent 31 percent cover in 2013 on the East amendment plot). The species composition (**Table 15 and Appendix B-14**) changed through time on these plots and is discussed below.

<u>East Plot</u>. Following clearing in December 2008, initial conditions in the East amendment plot included the loss of shrubs such as honey mesquite (*Prosopsis glandulosa*), which previously dominated the site. The honey mesquite community quickly transitioned to an early successional herbaceous plant community of higher canopy cover dominated by the non-native Russian thistle. By fall 2009, other native forbs, particularly golden crownbeard dominated the plot (**Table 13**). The invasive Russian thistle re-appeared in the fall 2010 along with an increase in the native species, golden crownbeard and carelessweed. Russian thistle was reduced to low levels by 2013, and the annual forb, golden crownbeard, continued to dominate the cover (63 percent) in 2013, with bristlegrass (*Setaria* sp.) the next most dominant species. These shifts in species composition differ from the reference plot, which was dominated in October 2013 by honey mesquite, carelessweed, and the native species, hog potato (*Hoffmannseggia glauca*) (**Table 13**). Though not amended or tilled, species composition in the East reference plot has also shifted substantially since 2010. The non-natives on the reference plot have remained minimal, however (assuming bristlegrass is a native). The aggressive annual, carelessweed (Bensch et al. 2003), has been slowly increasing in the study area since December 2008 (**Table 13**) and is now spreading more rapidly into reference plots as well as disturbed amendment plots. On the East reference plot, carelessweed had increased greatly by 2013 (to almost 30 percent cover), while broom snakeweed (*Gutierrexia sarothrae*) had disappeared from the sampled plots. After the amendment study was completed, a visit to the East plot in fall 2014 revealed that golden crownbeard was decreasing in abundance, allowing for grasses such as bristlegrass to increase (**Appendix C**).

<u>North Plot.</u> For the North amendment plot where clearing and tilling also occurred, the shifts in native versus non-native species composition were similar to those observed in the East amendment plot (**Figure 12** and **Table 13**). However, the North amendment plot did not show the reduction in cover of honey mesquite. Nonetheless, a short-lived early successional stage dominated by the invasive non-native Russian thistle as well as native carelessweed was observed following tilling (**Table 13**). After the non-native Russian thistle died back, vine mesquite (*Panicum obtusum*), a grassy native species, increased, and by fall 2010 the community was becoming more similar to the reference plot, with the exception of vine mesquite and non-native lambsquarters (*Chenopodium album*). By the fall of 2013, the non-native lambsquarters declined and an increase in the native carelessweed was observed. Carelessweed, a highly competitive species, dominated the amendment plot in 2013, though its abundance appeared reduced after the study when the plot was observed in fall 2014, though it was still present in 2016. In contrast, the North reference plot contains a community that is largely unchanged over time and is dominated by honey mesquite, scattered soap tree yucca, and a few minor herbaceous plant associates (North reference plot, **Table 13**). However, the reference plot showed signs of invasion by carelessweed in fall 2013. Note that the initial North reference plot (March 2008) was in a slightly different location than the plot measured following amendment/tilling, but it is assumed to have similar vegetation as its prior location.

<u>Northeast Plot</u>. The non-tilled Northeast amendment plot also demonstrated a shift in native/non-native species composition, with the non-native lambsquarters increasing in 2010 and disappearing by 2013. However, relative to the tilled plots, the non-native percentage was small just after the plot was amended (**Figure 12**). Other changes in the native community were also observed. Grasses such as sideoats grama (*Bouteloua curtipendula*) and blue grama (*Bouteloua gracilis*) decreased, while honey mesquite and

whiteball acacia (*Acacia angustissima*) increased (**Table 15**). New shrub species appeared with the addition of rabbit thorn (*Lycium pallidum*) and lote bush (*Ziziphus obtusifolia*), though other species classified as “shrubs” present before amendment application, such as sotol (*Dasylirion wheeleri*), yerba de pasmo (*Baccharis pteronoides*) and fourwing saltbush (*Atriplex canescens*), disappeared from the sample plots by 2013. The highly competitive annual forb, carelessweed, also increased in cover. Note that the initial Northeast reference plot (March 2008) was in a slightly different and less steep location (changed from 50 percent to 28percent, **Table 1**) than the plot measured following amendment/tilling. The original reference plot appeared to have more mesquite and fewer grasses than the moved plot. Nonetheless, the reference area around the Northeast plot has not changed considerably since the March 2008 pre-amendment sampling event. Carelessweed has not yet invaded the Northeast reference plot.

West Plot. In contrast to the other three treated areas, the vegetation community composition within the untreated West (control) plots showed less change over time. However by 2013, carelessweed increased and broom snakeweed disappeared from the sampled plots (**Table 13**). No non-native species occurred on the West plots (**Figure 12**). Because of the different geology of the area (e.g., Gila Conglomerate Formation), the vegetation community in the West plots is part of a different vegetation alliance than the other treated plots, as discussed above. It is part of the mixed grama herbaceous alliance, whereas the other three plots are in the mesquite/mixed grama alliance (Newfields 2005). Therefore, grasses and forbs typically dominate the West plots, with some honey mesquite and scattered wait-a-minute bush in the shrub stratum. A diversity of herbaceous species in the understory included, but was not limited to, sideoats grama (*Bouteloua curtipendula*), ring muhly (*Muhlenbergia torreyi*), Arizona three-awn (*Aristida arizonica*), and spreading three-awn (*Aristida divaricata*).

Considering the plots were not seeded, vegetation community re-establishment is on an expected trajectory toward eventual recovery. Notably, the return of life forms in proportions observed before the disturbance is still far from recovery and may require ten to twenty years to recover. Trends seen with an initial influx of Russian thistle and pigweeds (*Amaranthus* sp.) similar to carelessweed dominating the vegetation are not uncommon in plowed fields that are abandoned and not seeded (Piemeisel 1938). Therefore, the establishment patterns observed on the tilled plots of increasing domination by annual forbs the first five years are typical. For the untilled plot, the large reduction in grasses observed on the northeast amendment plot over time should shift with the eventual return of these grass species.

5. Changes in Species Composition Relative to Successional Patterns Seen in the Literature

Successional processes and rangeland condition affect vegetation establishment patterns and interact with the treatment results, and must be considered in the interpretation of the amendment study findings to avoid ascribing such changes to the treatment. The best way to evaluate these processes is to compare the species composition and successional trajectory of the disturbed treated plots to (1) the undisturbed reference plots to evaluate short-term 5-year effects and (2) published state-transition models in the region to evaluate longer term effects. Bestelmeyer et al. (2004) and the Natural Resources Conservation Service (NRCS) provide state-transition models for various ecotypes in the region. They provide information on long-term successional processes under different disturbances, management, and conditions (overgrazing, drought, soil additions, etc.). The following compares vegetation trends in the amendment and reference plots at each study location in relation to the state-transition models to identify how treatment has affected successional processes in the short-term and may affect such processes in the long term.

Northeast Plots. The northeast plots occur on southeast-facing slopes in the NRCS Hills ecotype, where shrubs, particularly succulents, as well as late successional grasses dominate in areas that are not heavily overgrazed. The expected late successional grasses in this ecotype are sideoats grama, black or blue grama, and tobosa. The northeast reference and untreated amendment plot, which were in fair rangeland condition, fit this description, having sotol (a succulent), bee brush, Yerba de pasmo (shrubs), sideoats grama, blue grama, and vine mesquite growing on the plots[1]. In contrast, once the plot was amended with lime and organic matter, it followed an initial trajectory of losing grasses and succulents, and becoming more shrub-dominated, which is typical in areas with overgrazing, soil erosion, and loss of soil fertility (**Figure 4** in Bestelmeyer et al. 2004). Though the organic matter addition should have increased soil fertility, the disturbance from the amendment application apparently was enough to transition the Northeast plot into a community similar to an overgrazed, eroded site. However, the return of sideoats grama, tobosa, and shrubs in a wet year in 2013, despite the invasion of the annual carelessweed, may indicate the Northeast plot will eventually return to a condition similar to the reference plot. Because the area is a semi-desert, the timeframe for species composition to return to its original state may be up to 215 years (Abella 2010), though perennial cover, currently about half that of the reference plot, may return more quickly. Abella (2010) reported that an average of 76 years was required for perennial cover in the Mojave and Sonoran deserts (up to elevations of 5,300 feet) to recover from disturbances such as fire or right-of-way maintenance.

At higher elevations more similar to Chino mine but without mesquite, Romme et al. (2003) studied recovery timeframes of semi-desert grasslands in the Uncompahgre plateau in Colorado. Their successional model describes disturbance by fire or prairie dogs initiating a successional sequence passing through the following three major stages:

- Early Grass: Forb and other herbaceous species are dominant, with a mix of annuals and perennials, and this stage persists from stand age 0 until age 20 to 30 years;
- Mid Grass: Shrub and herbaceous species are dominant, mostly perennials, with some shrubs becoming established, and this stage persists from stand age 20 to 30 until age 50 to 70 years;
- Shrub Dominated: Mix of mature shrubs and perennial herbs, and this stage persists from stand age 50 to 70 years until the next stand-replacing disturbance.

The above studies suggest that perennial cover may not fully return for 50 to 76 years and that a return to the original species composition could take much longer. This supports the study conclusion that steeper slopes in fair rangeland conditions, despite having high copper or pCu lower than the pre-FS RAC criteria, should not be amended to avoid long-term disturbance or erosion that would offset any benefit potentially obtained by soil amendments.

East Plots. The East plots are also in a Hills ecotype but on a relatively flat area. Bestelmeyer et al. (2004) report that on flat areas, this ecotype has more abundant grasses than on slopes. However, overgrazing can reduce the community to mostly shrubs (such as mesquite) and bare ground. The East reference plot matches the Bestelmeyer et al. (2004) description of an overgrazed community, and its rangeland condition is classified as poor. Over the long term, the East plot treated with tilling, lime, and organic matter will likely improve and respond in a manner similar to communities that received soil additions in Bestelmeyer (2004).

---

[1] Vine mesquite can colonize after disturbance as shown in **Table 15** in the North plot but also is common in late successional stage communities (Brock et al. 1978).

Such treatment should eventually return the vegetation to a community that supports perennial grasses including sideoats grama. Results suggest that the treated plot is on such a trajectory. In 2013, the treated plot had about one-third more vegetative cover than the reference plot. Vegetation consisted primarily of grasses and forbs, most of which were annuals (feather fingergrass, golden crownbeard, carelessweed). Perennial grasses are slowly increasing (sideoats grama, red threeawn) and perennial species indicative of overgrazing are decreasing (broom snakeweed, Sosabee et al. 1979). It may take a long time for the plot to recover to the species composition typically found in "good" rangeland in the Hills ecotype (Romme et al. 2003, Abella 2010, Bestelmeyer et al. 2004). Although recovery may be slow, the treatment clearly improved the condition of the site relative to the overgrazed reference plot.

North Plots. The North plots are in the loamy ecotype and were in fair rangeland condition. The reference plot and amendment plot before treatment were dominated by mesquite and yucca with some grasses such as vine mesquite, beardgrass, Arizona three awn, and sideoats grama. Loamy ecotypes in a mature, healthy state are usually grasslands (sideoats and blue grama) without shrubs, but are susceptible to mesquite invasion. With overgrazing and soil erosion, these ecotypes can become the mesquite/yucca/threeawn community observed at Chino in the reference plot and prior to treatment (Bestelmeyer et al. 2004). With droughts and more severe erosion, these areas can further degrade into annual-dominated communities (NRCS ecotype description).

After treatment by tilling, lime, and organic matter application, the North plot lost grass and yucca cover. Over time annual species dominated, though mesquite and the grass, vine mesquite, continued to comprise part of the community. Of the annual species, Russian thistle invaded first and died back, then lambsquarters, and lastly in 2013 carelessweed replaced lambsquarters and became abundant. Invasion by Russian thistle followed by other weedy annual species is a typical successional pattern following disturbance (Gelt 1993, Biondini et al. 1985). An increase in carelessweed also was observed on the North reference plot in 2013 and was probably due to the wet conditions of that year. Carelessweed invaded the West reference plot that year and was common in and around the phytotoxicity seed collection area (Arcadis 2017b) that year. Based on Hurley precipitation records from July through September, 2013 was similar to 2010; both years were wetter than other years of the study with the exception of 2008 (**Figure 14**). Carelessweed was more abundant in all four plots in the fall 2010 and fall 2013. In 2014, a drier year, carelessweed was not as abundant in the North plot, nor was it abundant in the seed collection area in 2016, a drier year similar to 2014 (see photolog in **Appendix C**).

Drought occurred in 2011 and 2012, which is known to favor mesquite over grasses (Bestelmeyer et al. 2014), and may have slowed recovery on the plot. Also, loamy ecotypes are prone to becoming degraded to annual-dominated communities from erosion and overgrazing (NRCS ecotype description) or drought. When the tilling and amendments were applied, the herbaceous component of the community degraded into annual competitive ruderal (e.g., pioneer) species (Redentde and Cook 1986) of thistle and lambsquarter during the early years of normal precipitation and became most dominated by the annual carelessweed species (also a ruderal) during the wet year of 2013. Based on a 2016 visit of the treated and reference plot (8 years after treatment), the treatment effects exacerbated by the drought in 2011 through 2012 and wet conditions favoring carelessweed invasion into barren areas in 2013 appear to be responsible for the degradation of the plot toward the annual-dominated state. During that visit, carelessweed was still relatively abundant and grass cover was low on the treatment plot relative to the reference plot (see photolog in **Appendix C**, with no carelessweed and more grasses observed in reference plot). Small gullies are present indicating that the plot may have eroded due to the tilling. To recover, it may require gully repair (soil addition) and seeding (NRCS ecotype description). However, erosion is also present on the reference plot, which has sustained its grasses.

West Plots. The west plots were not treated but show natural variability in community composition over time with climatic variability. The west plots are in the “Shallow” ecotype. This ecotype is a grassland with various types of gramas and ring muhly. With overgrazing, it degrades into a mesquite-dominated community (NRCS ecotype description), with an increase in broom snakeweed and ring muhly. The West plots are in fair to good rangeland condition and have very little mesquite invasion in the reference control plot and more abundant mesquite in the amendment control plot. Though the broom snakeweed shrub is common, these plots are mostly covered by grasses including sideoats grama, blue grama, and ring muhly. Similar to the other plots, rainfall increased carelessweed greatly on these plots in 2013. This supports the supposition that some of the increase in annuals on the treated plots is from rainfall as well as disturbance (**Figure 13b**). Based on field visits, the abundance of carelessweed has declined substantially on the West plots over the past several years (2014 and 2016), likely due to lower rainfall in those years (see photolog in **Appendix C**). Only the North amendment plot has maintained relatively high amounts of carelessweed.

In summary, except for the East amendment plot, the treatments did not move plots forward in succession toward an improved rangeland condition. Recovery to the condition before treatment may take decades. As discussed in Appendix B-21, the improvement in the East amendment plot may mostly be from the tilling activities decompacting the hard, rocky soil of a poor rangeland plot.

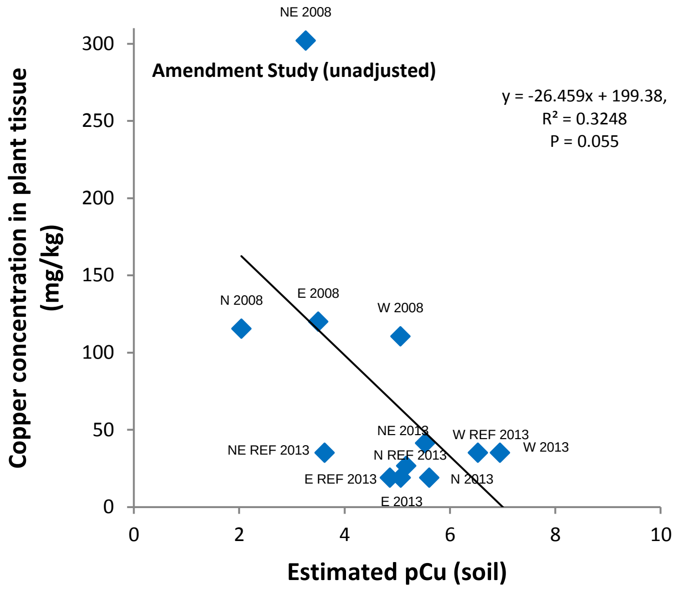
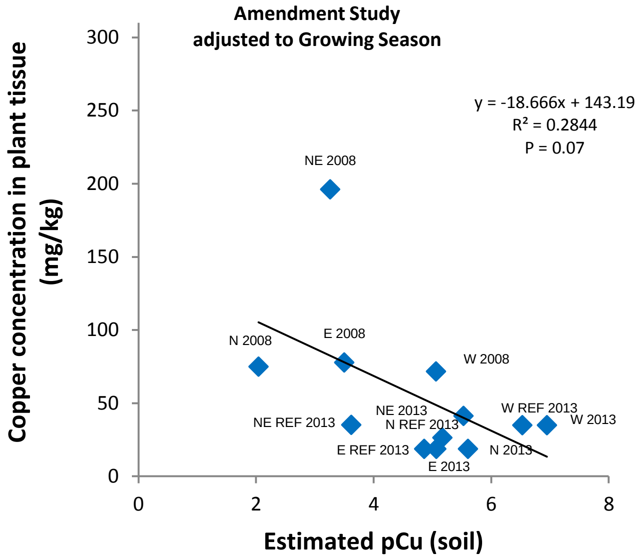
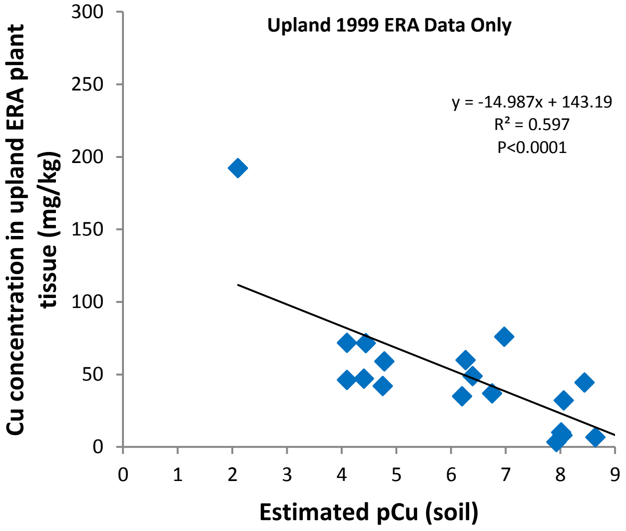
Northeast Amendment	2013	41.40	41.40	5.53
Northeast Reference	2013	35.23	35.23	3.62
West Amendment	early 2008	110.62	71.90	5.06
West Amendment	2013	35.20	35.20	6.95
West Reference	2013	35.19	35.19	6.53
Average of ERA plots	1999	76.00	76.00	4.48
Average of ERA Reference	1999	8.00	8.00	8.20

Note: pCu was estimated for March 2008 as if it were pre-white rain using 2006 pH data (in Table 1) because it is assumed March 2008 dormant plant tissues still represent pre-white rain condition. Early 2008 data are biased high relative to 2013 data in this table and associated graph because they represent dormant season tissue and other data represent growing season tissue.







Notes: Top graph shows amendment study data unadjusted for dormancy bias. Graph at bottom to left adjusted March 2008 tissue concentrations down by 35% to approximate growing season concentrations (whereas top graph shows dormant season concentrations for these plots). Graph at bottom right uses foliage and seeds combined (assuming 85% is foliage for grass and 95% for mesquite) to estimate tissue concentration from ERA data for upland plots ERA 1 to ERA 21. pCu is calculated. Data are original unwashed data, and would shift downward slightly if adjusted to washed by multiplying concentrations by 0.9282.

Notes:

1 - A = 5/2008 soil & 3/2008 vegetation sampling, B = December 2008 for both, C = October 2009, D = April 2010, E = October 2013. Vegetation sampling events "A,B, and C" are missing for reference plots (R added to cardinal directionabbreviated plot name) because no reference soil data available in 2008 and 2009. No "A" for West plot amendment because no soil lab data available for West plots in May 2008.

2 - Years 1 to 6 correspond to years 2008 to 2013

3 - Amended plot (A), reference plot (R), Amendment plot prior to amendment (B)

4 - Disturbance codes rank areas by the amount of disturbance from 5 (maximum disturbance immediately post-amendment/tilling) to 1 (5-years post-disturbance). Areas ranked 0 were pre-disturbance or control plots.

5 - Tilled (T), No-till (NT)

Codes for species are in Appendix B-9. Species cover percentages are non-CCP protocols.

Species Found on Amendment and Reference Plots

Year 5 Amendment Study Monitoring Report
Freeport-McMoRan Chino Mines Company
Vanadium, New Mexico

Species Common Name	Species Scientific Name	Species Code	Life Form	Season
Whiteball acacia	*Acacia angustissima*	*ACAN*	Forb	
Acacia seedling	*Acacia sp.*	*ACSP*	Forb	
Wild onion	*Allium macropetalum*	*ALMA*	Forb	
Bee brush	*Aloysia wrightii*	*ALWR*	Shrub	
Carelessweed	*Amaranthus palmeri*	*AMPA*	Forb	
Crested anoda	*Anoda cristata*	*ANCR*	Forb	
Arizona three awn	*Aristida arizonica*	*ARAR*	Graminoid	warm
Six week three-awn	*Aristida adscensionis*	*ARAD*	Graminoid	warm
Purple three-awn	*Aristida purpurea*	*ARPU*	Graminoid	warm
Spreading three-awn	*Aristida divaricata*	*ARDI*	Graminoid	warm
Vetch species	*Astragalus sp*	*ASSP*	Forb	
Four wing saltbush	*Atriplex canescens*	*ATCA*	Shrub	
Desert holly	*Atriplex hymenelytra*	*ATHY*	Shrub	
Unidentified saltbush	*Atriplex sp.*	*ATSP*	Shrub	
Yerba de pasmo	*Baccharis pteronoides*	*BAPT*	Shrub	
Hairyseed bahia	*Bahia absinfolia*	*BAAB*	Forb	
Beardgrass	*Bothriochloa barbinodis*	*BOBA*	Graminoid	warm
Side-oats grama	*Bouteloua curtipendula*	*BOCU*	Graminoid	warm
Blue grama	*Bouteloua gracilis*	*BOGR*	Graminoid	warm
Sixweeks grama	*Bouteloua barbata*	*BOBA2*	Graminoid	warm
False mesquite	*Calliandra humilis*	*CAHU*	Forb	
Mountain mahogany seedling	*Cercocarpus montanus*	*CEMO*	Shrub	
Baby aster	*Chaetopappa ericoides*	*CHER*	Forb	
Lambsquarters	*Chenopodium album*	*CHAL*	Forb	
Narrowleaf goosefoot	*Chenopodium leptophyllum*	*CHLE*	Forb	
Feather finger-grass	*Chloris virgata*	*CHVI*	Graminoid	warm
Knifeleaf condalia	Condalia spathulata	*COSP*	Shrub	
Bearded dalea	*Dalea pogonathera*	*DAPO*	Forb	
Sotol	*Dasylirion wheeleri*	*DAWH*	Shrub	
Tick clover	*Desmodium sp.*	*DESP*	Forb	
Purple or hoary aster	*Dieteria sp.*	*DISP*	Forb	
Dogweed	*Dyssodia papposa*	*DYPA*	Forb	
Snakeweed	*Gutierrezia sarothrae*	*GUSA*	Forb	
Annual goldeneye	*Heliomeris longifolia var. annua*	*HELO*	Forb	
Curly mesquite	*Hilaria belangeri*	*HIBE*	Graminoid	warm
Hog potato	*Hoffmannseggia glauca*	*HOGL*	Forb	
Crestrib morning glory	*Ipomoea costellata*	*LPCO*	Forb	
Rabbit thorn	*Lycium pallidum*	*LYPA*	Shrub	
Slender goldenweed	*Machaeranthera gracilis*	*MAGR*	Forb	
Tansy aster	*Machaeranthera tanacetifolia*	*MATA*	Forb	
Blackfoot	*Melampodium leucanthum*	*MELE*	Forb	
Many flowered blazing star	*Mentzelia multiflora*	*MEMU*	Forb	
Wait-a-minute	*Mimosa biuncifera*	*MIBI*	Shrub	
Unidentified Muhlenbergia	*Muhlenbergia sp.*	*MUSP*	Graminoid	warm

Appendix B-9
Species Found on Amendment and Reference Plots

Year 5 Amendment Study Monitoring Report

Average of Pooled Data for Amended Plots (Excludes West)	**132.93**		**25.04**	**31.44**		

Notes:

1-Copper is not adjusted to remove dormancy bias in first column but is in second column. This table presents all unwashed data because 1999 and 2008 data have no washed data (multiply all by 0.9282 to convert to washed or see Appendix B-18 for washed data).

2 - Assumes 15% of dry weight is seeds, 85% is foliage (Griffith 2000) for grasses, and 5% of dry weight is seed for mesquite (based on percent biomass collected in 2008 and 2013).

3 - Sites with pH < 5.5 before white rain include Northeast, East, and North Amendment Plots and ERA 1,2,3,4,7,9,10,13. Only ERA sites with pH < 5.5 are in this table.
Values are milligram per kilogram (mg/kg).

ERA = Ecological Risk Assessment (Newfields 2005 has 1999 data for ERA plots)

Appendix B-17

Average of Pooled Data for Amended Plots (Excludes West)	**123.38**		**23.49**	**32.62**		

Notes:

1-Copper is unadjusted in first column and adjusted to remove dormancy bias downward by 35 percent in second column. This table presents all data that are washed samples or adjusted to washed samples and is the same table as Appendix B-16 but adjusted to washed, rather than unwashed conditions

2 - Assumes 15% of dry weight is seeds, 85% is foliage (Griffith 2000) for grasses, and 5% of dry weight is seed for mesquite (based on percent biomass collected in 2008 and 2013).

3 - Sites with pH < 5.5 before white rain include Northeast, East, and North Amendment Plots and ERA 1,2,3,4,7,9,10,13. Only ERA sites with pH < 5.5 are in this table.

Values are milligram per kilogram (mg/kg).

ERA = Ecological Risk Assessment (Newfields 2005 has 1999 data for ERA plots)

Data Used to Develop OAT Scores and Rangeland Condition Ratings of Amendment Plots

Year 5 Amendment Study Monitoring Report
Freeport-McMoRan Chino Mines Company
Vanadium, New Mexico

Plot	Year/ ID	vigor (max = 10)	seedlings (max = 10)	surface litter (max = 5)	pedestals (max = 5)	surface crusting (max = 5)	rills/gullies (max = 5)	OAT score (sum)	Rangeland Condition[1]
1997 OAT Score Rating[2]									
EAST	1997/HE216	2	2	1	3	2	3	13	POOR
WEST	1997/HW111/165	8	8	3	3	3	4	29	GOOD-FAIR
NORTH	1997/HW168	7	7	4	4	4	4	30	FAIR
NORTHEAST	1997/HE192	8	7	5	4	5	4	33	FAIR
2011 (West, North, Northeast) or 2014 (East) OAT Score Rating[3]									
EAST	2014/reference	3	5	2	5	1	3	19	POOR
WEST	2011/reference	9	8	5	5	5	5	37	GOOD-FAIR
NORTH	2011/RS map	--	--	--	--	--	--	≥ 22	GOOD-FAIR
NORTHEAST	2011/RS map	--	--	--	--	--	--	≥ 22	GOOD-FAIR

1 - Rangeland Condition in 1997 was based on OAT score rating and other soil and vegetation condition factors (see Table B-1 in Woodward Clyde 1997 and Data sheets in Appendix D), whereas in 2011 and 2014 it is based only on OAT score, assigned good-fair if above 22, and poor if equal to or below 22.

2 - OAT scores are described in Arcadis (2011a).

3 -East and West plots were surveyed in field with ratings for criteria to develop OAT score. North and Northeast rating was based on remote-sensing based map of predicted OAT scores.

max = maximum possible score of range unit in potential condition for area.

1 - A one-sample t-test on arcsin square-root transformed proportions or non-parametric equivalent test (if t test assumptions not met, Wilcoxon one-sample test used) between 2008 value and average of five periods of sampling were compared using data in Appendix B-20b. P values are included to evaluate if variability is too high (if P ≥ 0.10), making comparison of pre- to post-effect periods in Table 16b uncertain.

Red are from Wilcoxon one-sample tests

Appendix B-21: Weight of Evidence on Separate Effects of Three Technologies

The amendment study was not designed to evaluate each treatment's effectiveness on improving wildlife habitat and rangeland separately, yet the Feasibility Study (FS) will need such information for remedial decisions. This section attempts to evaluate each treatment separately by gathering evidence from five sources: (1) this study, (2) the site-wide ERA (Newfields 2005), (3) the white rain report (Arcadis 2017a), (4) the phytotoxicity and community report (Arcadis 2017b), (5) photographs and anecdotal observations of the results of haul road tilling and (6) from the literature. The effect of lime alone is best evaluated by assessing white rain effects. The effect of tilling alone is best evaluated by assessing haul road tilling effects, where a haul road in a poor rangeland area was "ripped" just as the East plot was ripped (ripping and tilling are both referred to as tilling in this report). The effect of organic matter amendments is best assessed by comparing effects of organic/lime amendment applications to untreated plots, to the Northeast amendment plot where the lime had no effect on pH or pCu, and to areas treated without organic matter, such as the haul road. The latter requires subjectively separating lime from likely organic amendment effects, which is tenuous at best but strengthened by reviewing the literature on effects of organic matter on reclaimed lands. Effects on soil chemistry, copper uptake, and plant community parameters of vegetative cover, richness, percent of vegetation in grass cover, and successional stage were compared for each individual technology. This approach weights the evidence to make final conclusions on effectiveness of the technologies. This appendix is included to reduce likelihood of making conclusions based on the uncertain amendment study that may not be warranted when other information sources are evaluated.

Lime Effect based on White Rain

The white rain was a "natural" event and its effect on soil chemistry was documented across the Smelter Tailing Soils Investigation Unit (STSIU) in the *Year 5 Report on pH Monitoring to Evaluate the Effect of White Rain on STSIU* (referred to as the white rain report, Arcadis 2017a). Based upon the work done to analyze the effects of the white rain, there is a robust set of information to support an independent analysis of lime as a remedial technology because the constituents detected in the white rain were essentially the same constituents in lime (i.e., calcium oxide and hydroxide). The white rain analyses supported that lime in the rain significantly increased pH and pCu.

The white rain effect on vegetation in the amendment study plots is discussed in the main text of this report. The change in pCu from the white rain appeared to substantially reduce copper uptake in aboveground tissue (**Figure 6** of main report[1]). As discussed in the main text, this reduction in uptake likely affected community composition by increasing plant species richness and the proportion of cover that is herbaceous, as shown by the higher richness and proportion in non-woody cover in all the reference plots in this study (**Figure 9b, Table 16a and 16b**). The white rain did not improve total vegetative cover, and cover decreased on one plot (Northeast), though its proportion in grass species increased some.

Other reports provide additional supporting information on the effect of the increased pCu from the white rain on vegetation community characteristics. The phytotoxicity and community study (Arcadis 2017b, referred to as the community study) identified positive relationships between pCu with cover and richness,

---

[1] Figures and Tables refer to those in main report unless indicated otherwise.

which can be tested as to whether they hold true with amendment study data. It also provides lists of species found on subplots of some ERA locations and amendment plot locations in 2014 after the white rain (**Appendix F, Table F-3**) that can be compared to such information recorded before the white rain in this study and in the site-wide ERA 1999 study. No remedies were applied to the study areas in the community study or to the plots evaluated, enabling an assessment of just the white rain effect.

The community study found species richness was higher on soils with higher pCu, but only when the soil category was taken into consideration. The four soil categories were (1) rocky, eroded soils on relatively flat areas represented by the East area in this study (called flat rocky), steeper slope soils (>13 percent) represented by the Northeast area (called slope), granular soils on relatively flat ground represented by the North and West areas (called flat granular), and bedrock soils in areas with over 60 percent bedrock at surface (called bedrock, **Figure A-2-2**). The bedrock type is not represented by any plot in this amendment study but the other three types are.

Bedrock locations had the lowest richness at the same pCu, followed by rocky soils. The flat, granular soils had the highest richness for a given pCu and slope soils the second highest. The community study found total cover was significantly related to pCu only in the flat granular and bedrock types.

The community study results were mostly consistent with the white rain results. The community study result showed richness increases with increasing pCu, consistent with the higher pCu from the white rain increasing richness on the reference plots. Unlike richness, percent total vegetation cover did not increase with certainty on the reference plots after the white rain (**see reference plots in Table 16a, Figure 9a, Figure 10 and photolog in Appendix C**). The community study also found no relationship between pCu and cover in slope or flat rocky soils, but it did for flat granular soils. The North reference plot had flat granular soil, and its cover increased with increased pCu by 25 percent by 2013 (**Table 16a**), which would be consistent with the community study; however, that increase is highly uncertain because of high variability in cover in that plot over time (**Figure 9a**). The West plots also had flat granular soils, yet vegetative cover did not increase after the white rain, probably because the West plots already had high pCu before the white rain.

Soil pCu might have a more important effect on non-woody cover than total cover, particularly forbs; however, the increase in proportion in grass species after the white rain was small to nonexistent (**Table 16b**). On the relatively barren mesquite-dominated East reference plot (flat rocky type), a grass species did appear briefly in the single monitored 11-foot radius subplot (subplot is 4 percent of the plot), specifically, sand dropseed (*Sporobolus cryptandrus*). It appeared in 2010, but was not there in 2013. It and beardgrass were present again in small amounts on the plot in 2014 when more (25 percent) of the plot was surveyed as part of the community study (Arcadis 2017b).

ERA plot plant community observations and soil pCu before (Newfields 2005) and after the white rain (Arcadis 2017b) are shown in the Table B-21-1 below in addition to poor rangeland reference plot observations (pre-white rain amendment and ERA plots are comparable because same sized plot, though longer shape of ERA plots may results in more species[2]). These table comparisons are for flat rocky soils, which are in poor rangeland condition. Vegetation abundance changes with weather, but fortunately data

---

[2] See Arcadis (2017b) discussion of likelihood of observing more species in ERA plot shape.

compared in the **Table B-21-1** were collected during the fall season in years with similar rainfall (**Figure F-5** in Arcadis 2017b).

Table B-21-1. Observations before and after the white rain.

	ERA 2		ERA 3		East Reference	
	Before (1999)	**After (2014)**	**Before (1999)**	**After (2014)**	**Before (Mar 2008)**	**After (2014)**
Soil pCu[1]	4.1	5.7	4.4	5.6	4.2	5.3
Richness	1	9	6	11	3	12
No. grass species and code[2]	0	2 (ARPU, SPCR)	2 (SEMA, SPCO)	2 (SESP, BOBA)	0	3 (BOBA. SPSP, BOBA2)
No. forb species	0	5	2	7	1	6

No. succulent species	0	1	0	0	0	0

Notes:

1 – Calculated pCu; In Arcadis (2017b), where STS-PT-2013-1 is ERA 2, STS-PT-2013-2 is ERA 3, STS-PT-2013-17 is East Reference Plot of Amendment Study.

2 – Species name associated with species code is in **Appendix B-9**.

The table shows number of all species increased by up to 9 species and forbs increased by 5 species when pCu increased after the white rain. When pCu was improved on rocky soils with pCu less than 4.3 to over 5.0 (ERA 2 and East reference plots), up to 3 grass species per plot returned (various combinations of red threeawn [*Aristida purpurea*], beardgrass [B*othriochloa barbinodis*], bristlegrass [*Setaria* sp.], dropseed, and sixweeks grama [*Bouteloua barbata*]). At slightly higher pCu before the white rain in ERA 3, two grass species were already present (bristlegrass and dropseed); two grass species were still present (bristlegrass and beardgrass) after the white rain in that plot. Grass species most responsive to the white rain on these soils are beardgrass (BOBA), red threeawn (ARPU), and sixweeks grama (BOGR). Forb species responsive include silverleaf nightshade (*Solanum elaeagnifolium*), globemallow (*Spheralcea* sp.), cottonbatting plant (*Pseudognaphalium stramineum*), and babyslippers (*Hybanthus verticellatus*) (Arcadis 2017b). Hog potato (*Hoffmannseggia glauca*) and Abert's wild buckwheat (*Eriogonum abertianum*) may be more tolerant of low pCu as they were present on the ERA plots before the white rain (Newfields 2005). Hog potato showed up after the white rain on the East reference plot (**Table 15**). Despite more species, large changes in cover in this rocky habitat did not occur as seen in photographs below of conditions before and after the white rain. However, the proportion of the limited cover present in non-woody plants increased in the low pCu plots (**Table 16b**) Photographs of ERA 2 and ERA 3 plots prior to white rain are below:

Photo 1. ERA-2 in Spring 2000 (from Arcadis 2001)

Photo 2. ERA-3 in Spring 2000

Photo 3. ERA 3 in Fall 1999

Fall photographs of ERA 2, ERA 3, and East reference plots after the white rain are below.

Photo 4. ERA 2 in Fall 2014

Photo 5. ERA 2 in Fall 2014

Photo 6. ERA 3 in Fall 2014

Photo 7. ERA 3 in Fall 2014

Photo 8. ERA 2 in Fall 2013 (grassy tilled haul road in background is not part of plot)

Photo 9. ERA 3 in Fall 2013

Photo 10. East reference plot in Fall 2016

For fair rangeland soils that are flat, granular (North reference plot) or slope soils (Northeast reference plot), species composition shifted some in the Northeast reference plot (more vine mesquite) but not in the North reference plot after the white rain (**Table 15**). The status of the successional stage did not seem to be strongly affected by the white rain in either of these plots because no shifts from mostly early to late successional species were observed (stages are described in **Section 5** of **Appendix B-3**).

In conclusion liming alone, as seen by the white rain, can increase soil pH and pCu; decrease copper uptake into plants; and increase species richness and the proportion of existing cover in non-woody plants (also see main text). The increase in soil pH and pCu is smaller on the steep plot because of runoff. On all the plots, effects on cover, grass proportions, and successional stage appear to be at most minimal. The effect of the white rain as a lime treatment alone based on the weight of evidence is summarized in **Table 20**. Lime is not recommended as a stand-alone treatment because it did not increase vegetative cover, which is required to improve habitat for wildlife and livestock.

Tilling Effect Based on Ripped Haul Road

As discussed in the main text, tilling or plant disturbances must be added or replace the lime amendment to change grass and perennial herbaceous plant cover as well as successional stage. The plant community change from tilling with amendments (lime and organic matter) observed on the amendment plots was in a positive direction on the flat rocky poor rangeland type and in a negative direction on the fair rangeland slope and flat granular types. To separate which of these changes are solely due to tilling, the ripped (tilled to 12 to 18 inches in 2003) haul road results were evaluated. No amendments were added to the road, and the white rain occurred five years later enabling an independent analysis of the effects of tilling without confounding variables due to chemistry. This discussion of tilling effects is restricted to the soil categories of the North and East plots because steep, boulder-ridden slopes such as the Northeast plot are impractical to till.

Tilling without amendments reduces soil compaction and creates a more penetrable granular growth medium, which is of most benefit in soils that are compacted or have lost surface soil, such as the East plots of the flat rocky type. Tilling also mixes the soil and its constituents more evenly to deeper strata. The North and West plots are in better rangeland condition, already have granular soils and greater amounts of established vegetation; therefore, tilling would do more harm destroying established vegetation than good in these plots. The tilling effect is discussed first for the flat rocky soil category using the haul road as an example because the haul road represented the flat rocky type in poor rangeland condition since it was adjacent and built on that type. The possible effect of tilling alone for the flat granular category is then discussed but no local example of tilling alone is available in fair rangeland areas.

<u>Flat Rocky Soil Category</u>. Before tilling, the haul road was adjacent to and composed of a rocky, compacted soil in a relatively level area that had been overgrazed with loss of surface soil. The tilling, accomplished with a ripper similar to the one used for the East plot, created furrows of granular, mixed soil in which new species grew. At first Russian thistle grew in the furrows; three years after the tilling, the thistle was replaced by grasses, based on anecdotal information (Pam Pinson, personal communication). The pCu of this area before tilling is estimated to be in the general range of the ERA 2 plot in 1999 of 4.1 because it is immediately adjacent to the ERA 2 plot, a plot with the same type of rocky substrate (**Photo 9**). The road before tilling is assumed to have had very little vegetation because it was a haul road, but adjacent areas approximated the plant community at the ERA 2 location in 1999 (shown in **Table B-21-1** above as only having one species, honey mesquite). The grass species of the post tilling and post-white rain community on the road were observed in the field and photographed in 2014 for comparison, showing more abundant grasses of at least six species than observed in the adjacent area in 1999 (**2014 Photos 11 to 13** of haul road below). Because the white rain occurred between 1999 and 2014, it is also useful to compare the species composition of the tilled road in 2014 to the recorded species composition of the similar East reference plot in 2014 (from the Arcadis 2017b community study), as the former has been tilled and exposed to the white rain and the second has not been tilled but was exposed to the white rain. The untilled ERA 2 community in 2014 can also be compared to the tilled road as shown in the **Table B-21-2** below. The differences may be attributable to the tilling.

Table B-21-2. Observations before and after the white rain compared to after tilling and white rain[1].

	ERA 2 Before White Rain (1999)	ERA 2 after White Rain (2014)	Adjacent Haul Road After Tilling and White Rain (2014)
Soil pCu	4.1	5.7	> 5.7[2]
Richness	1	9	≥ 8
No. grass species and code[1]	0	2 (ARPU, SPCR)	≥ 6 (SESP, ARSP, SPSP, BOCU, BOBA, BOGR)
No. forb species	0	5	≥ 1
No. shrub species and code	1 (PRGL)	1 (PRGL)	≥ 1
No. succulent species	0	1	0

Notes:

1 – Name of species code is in **Appendix B-9**, except ARSP is *Aristida* sp.

2 – Probably higher than pCu of adjacent ERA 2 area because tilling may have mixed in copper at surface with lower subsurface and increased pCu to even higher levels than the white rain.

The number of species growing in the tilled haul road is uncertain because small species can be missed in the photographs, but at least 8 were identified based on fall 2014 photographs (**Photos 10 to 12** below) and probably more. That change could be ascribed to the white rain, which also increased species (by 8) in the adjacent ERA 2 plot. The dramatic change from tilling alone, however, was the percent cover in grasses and number of perennial grass species. The tilled haul road after the white rain had a high abundance and cover of bristlegrass, red threeawn or Arizona three-awn (*Aristida arizonica*), sand dropseed, sideoats grama (*Bouteloua curtipendula*), a small amount of beardgrass, and blue grama (*Bouteloua gracilis*) or other gramas in the furrows. Not as much grass cover was in between the furrows, where the soil was not tilled. Grasses dominated, outcompeting forbs though some forbs and shrubs were present (see photos below). The similar ERA 2 plot had much lower cover of grass species the same season and year, composed of red threeawn and sand dropseed (**Table B-21-2**, **Photos 4 and 5**). The number of grass species was at least 4 greater in the tilled road, than the untilled adjacent ERA 2 plot (**Table B-21-2**). In comparison, the similar but untilled East reference plot in fall had a low amount and number of grass species (**Photo 10 and photolog in Appendix C**) that were mostly beardgrass with some sand dropseed and sixweeks grama. The untilled ERA 3 plot in 2014 also had few grass species (only 2) and grass cover was sparse: beardgrass and bristlegrass (**Table B-21-1**, **Photos 6 and 7**). The late successional sideoats and blue grama species were only present in the tilled haul road (the grama species successional status are discussed in Bestelmeyer et al. 2004).

These observations, though more qualitative (percent cover by species was not recorded), indicate tilling can increase grass cover and accelerate succession toward late successional species such as blue grama and sideoats grama after 11 years when compared to nearby areas without tilling. These results apply to tilling to 12 to 18 inches, which is deeper than tilling that occurred for this Amendment Study (8 inches), but tend to match results observed in the East amendment plot of increased total cover and grass cover, except for more late successional grass species and fewer annual weeds were thriving on the tilled haul road (compare **Photos 11 to 13** with **Photo 14**). The East amendment plot in 2014 represents a location with rocky, eroded surface soil in poor rangeland condition that was tilled but more completely and at shallower depth and limed twice (white rain, amendments) to a pCu of 6.2, plus it had organic amendments added. Unlike the tilled haul road, it was dominated by forbs in 2013 and 2014 (and 2016) but nonetheless also had abundant grasses, where the grass species were dominated by bristlegrass and localized patches of feather fingergrass, with some sideoats grama and red threeawn. It had 6 forbs and 3 shrub species, with forbs dominating (**Table 15, Appendix B-14, photolog in Appendix C**). This difference in forb versus grass dominance may be because more years have passed since tilling the haul road (11 years) than on the East plot (6 years), or due to addition of amendments on the East amendment plot producing different results. The tilling plus amendments applied to the East amendment plot converted it from “poor” to “good” rangeland condition (see main text) but also encouraged weedy annuals to invade. Tilling on the East plot could have also reduced copper concentrations by mixing the surface with low concentration subsurface soils during the decompaction and not have needed the white rain or organic amendments. But the decompaction alone could produce the results observed if the plants are resistant to low pCu. Most likely the large increase in cover in both the haul road and East plot is a from a combination of decompaction and mixing with depth. Decompaction may have been the main driver because pCu was high (5.7) in the adjacent area of the haul road (**Table B-21-2**), yet did not show the same cover and grass improvement.

Photos 11 to 13: Haul Road after “tilling” in 2014.

Photo 11. Fall 2014

Photo 12. Fall 2014

Photo 13. Fall 2014

Photo 14. East amendment plot in fall 2014 after tilling with lime and organic matter amendments

Overall, the comparisons suggest the tilling in the eroded rocky soil type characterized as in poor rangeland condition increases grass cover to a much greater extent than the white rain or lime amendments. The grass species present after tilling alone in the haul road include more late successional species over time than if the area were not tilled and only subjected to the white rain. In contrast, the East amendment plot tilling combined with amendments resulted in mainly the early successional species of bristlegrass, threeawn, and dropseed (and often beardgrass) establishing early after disturbance. They are often early colonizers based on the literature (Roemer and Schultes 2010, Hu et al. 2013; FEIS database, https://www.fs.fed.us/database/feis/plants/graminoid). The CCA in **Figures 13a and 13b** further supports that bristlegrass, threeawn, and feather fingergrass are early colonizers after tilling, but the threeawn can also be a late successional species and may also be influenced by lime amendments increasing pCu and pH. (see main text and **Figures 13a and 13b**). The tilled haul road results indicate, however, that apparently two of these grass species (bristlegrass and threeawn) can increase after tilling despite no additional lime treatment beyond the white rain. The white rain, however, increased pH substantially in the haul road, probably the same increase as seen in the adjacent ERA 2 plot area (increase of 1.6 standard units).

The tilling might have changed the pH or pCu of the tilled haul road soils by mixing and dispersing copper and hydrogen ions, but these soils have not been sampled to verify if the soil chemistry changed. Large differences in soil chemistry of the surface six inches are unlikely with tilling only to eight inches, as seen by no significant large and detectable changes in copper resulting from tilling the amendment plots (**Table 9a**), but the haul road was tilled to 12 to 18 inches and may have had more of a mixing effect. Because there is no clear benefit of all three remedial technologies in increasing pCu and decreasing uptake of copper in plants in the East amendment plot after the white rain, this suggests that chemical changes from mixing are not driving the large community changes, but rather the tilling to convert poor rangeland to fair to good rangeland is responsible. The evidence from the road tilling also supports that copper uptake in plant tissues probably is less of an impediment to a healthy grass and rangeland community than soil loss and compaction, which in many areas stems from past overgrazing.

Overgrazing was widespread in the area, however, we cannot assess how much of the soil loss and compaction observed today was either a result of past pCu depression or overgrazing. More than 55 percent of the pCu value less than 6 area is Muzzler Rock Outcrop/Santana. The Soil Conservation Survey (SCS) classifies these soil types as “very poor” for grasses, indicating that restrictions for the element or kind of habitat are very severe and that unsatisfactory results can be expected. The Grant County SCS indicates that steepness of slope, depth to bedrock, areas of rock outcrop, and small stones are major limitations and overgrazing leaves the soils in this unit subject to soil blowing and gulling, resulting in an increased number of undesirable plants. Other soil types in the pCu valueless than 6 area include Abrazo Luzena, Dagflat, Lonti, Manzano and Pay-Ell-Man. Historic grazing practices occurred over the past 100 years, before the first smelter stack was built in 1910. Prior to the turn of the century, there were no fences and there were uncontrolled numbers of livestock grazing. In the early 20th century, land went into private ownership and fences were built. Modern day grazing practices are significantly improved; however, early grazing had an effect and impacted the soil.

Flat Granular Soil. Little information is available on the effect of tilling alone on STSIU vegetation communities on the flat granular soil type because no area has been tilled on this type without adding amendments of lime and organic matter. However, all three treatments combined reversed positive trends of the white rain and caused a reduction in plant species diversity (evenness) and percent in grass cover after 5 years (**Tables 16a and 16b**). This reduction is not unexpected because a granular soil located in an area with fair rangeland condition does not need decompacting and would already have good grass growth, as long as low pCu was not too limiting. The North amendment plot had acidic soil with low pCu (estimated to be about 2.0 based on current copper concentrations, **Table 1**) during the growing season before the white rain. Yet, it had grass species and plant diversity that were lost after the treatments were applied. The evidence supports that copper uptake in plant tissues is less of an impediment to a healthy grass and rangeland community for fair rangeland than disturbance that can set succession back to an earlier stage. In contrast, the results from the rocky soil type indicate decompaction through tilling is a primary driver for increasing vegetative cover, particularly grass cover. The white rain effect of increased diversity and proportion in herbaceous cover (though not more grass or total cover) shows the fair rangeland community can improve somewhat with liming, but tilling and possibly organic matter additions remove that benefit. Based on a review of successional processes (**Section 5** in **Appendix B-3**), it may be decades before this soil type can recover from the tilling and organic matter application.

For example, late successional species such as sideoats grama as well as Arizona three-awn were already growing on the North amendment and reference plots in highly acidic soil (pH = 3.69, Table 1) before the white rain and treatment (as well as beardgrass and vine mesquite). Tilling clearly eliminated these and set back the community to an earlier annual weedy successional stage, which has not yet recovered. Weedy annuals dominated the North amendment plot even eight years later in 2016 (see photolog in **Appendix C** with abundant carelessweed). Some sideoats grama and sand dropseed were present in 2013 (**Appendix B-14**) indicating some movement toward a later successional stage, but the process is slow because mainly vine mesquite (a grass) was present in 2016 (see photolog in **Appendix C**). The lime and organic matter may have contributed to the setback in grasses, as seen by the reduction in grass cover percentage in the Northeast amendment plot that was not tilled, but the Northeast amendment plot did increase in cover whereas the North amendment plot did not after 5 years. That difference in total cover may be a result of tilling, not from the organic matter.

The results support that plots in fair rangeland condition with grasses may not benefit from tilling, which is often observed in the literature when semi-desert areas are disturbed (Romme et al. 2003, Bestelmeyer et al. 2004), especially since perennial grasses take a long time to recover (see **Section 5** on vegetation succession in **Appendix B-3**). In contrast, poor rangeland will benefit from decompaction of the soil improving total cover, grass cover, richness and advancing succession toward a more perennial plant community of good rangeland quality. **Table 20** summarizes this conceptual model of the effect of tilling on community parameters on rocky and flat granular soil types based on the weight of evidence discussed in this section.

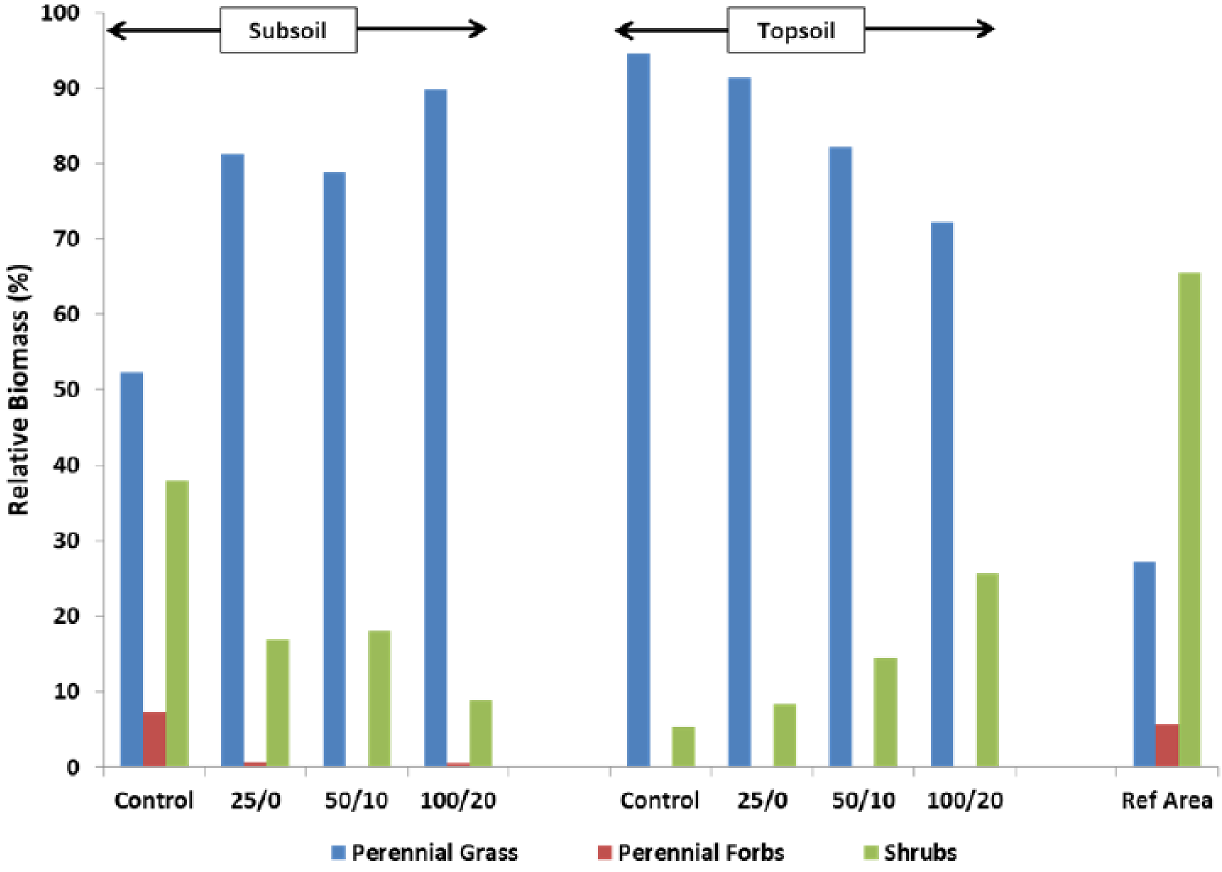
Effect of Organic Matter

The organic matter did not appear to contribute to a change in pH or pCu based on finding that (1) neither the lime nor organic matter increased pH or pCu when both were applied together on the Northeast plot and (2) even the other two plots did not show a significant increase in pCu relative to the untreated reference plots after these amendments were applied. Lime applied on acid soils is known to increase pH and it did improve pH when tilled into the soil, but was not effective at significantly changing the pCu, even when combined with organic matter. With greater sampling, a significant change may have been detected but the change most likely is attributable to the lime increasing the pH. Organic matter was not applied on the tilled haul road and yet the grasses greatly increased in cover and diversity, indicating organic matter may not be particularly important for altering soil chemistry and improving plant communities.

Organic matter possibly could improve structure of the soil and release of nutrients to plants and its addition may further enhance the community beyond tilling effects. However, the effect of organic matter on the plant communities is difficult to estimate from this study because it was not applied separately. The literature includes studies that applied it separate from other amendments and can provide insight into its effectiveness. Reclamation staff (Dr. Lewis Munk) at Chino reviewed many studies of reclamation in semi-arid to arid areas in New Mexico, Arizona, Utah, and Colorado and found the studies generally reported little to no benefit of adding organic matter to topsoil or cover material when reclaiming areas. Paschke et al. (2005) found no improvement in perennial species relative to controls after 25 years when biosolids (treated sewage) were applied to topsoil at a shale retort mine in Colorado, and plant diversity decreased (**Figure B-21-1**). Bay et al. (2010), in a limestone quarry study of manure amendments in New Mexico, found that after 5 years, annual weeds dominated (Russian thistle and kochia) and richness and vegetation cover did not improve over controls (**Figure B-21-2**). Walton et al. (2001) found no effect of biosolid amendments on vegetation of degraded rangeland after 18 years in a study on the Jornada Experimental Range in southern New Mexico. Milczarek et al. (2011) conducted a 13-year study on Morenci mine in Arizona and found that high rates of biosolids application on acidic tailings covered with a foot of cover material or more (biosolids applied at 3 rates similar to this study) increased salinity and weedy annuals and decreased diversity, though overall vegetation cover increased as the amount of organic matter added increased (Photos 15 to 17). Some sites have weed dominance even 10 years after application (cheatgrass invasion, Borden and Black 2011; biosolid treatment in Utah) and some do not (good grass growth, Ippolito et al. 2010; 14-year Colorado study), though the latter was on non-degraded rangeland, applied for biosolid disposal, not reclamation. These studies do not address changes in pCu from organic matter additions but the current amendment study does not strongly support that pCu changes after applying lime or organic matter amendments (**Table 9a and 9b**), and as such results from these studies may be applicable to the likely effect of organic matter additions at the STSIU.

The conclusion from the review of these various studies of little benefit from organic matter amendments seems consistent with results discussed in this appendix. The tilled haul road had an increase in total cover, grass cover and grass species richness without organic matter or lime (other than white rain) added, which supports that reducing compaction at the surface of poor rangeland soils (after liming by the white rain) assisted plant and grass growth, not the addition of organic matter. The more steeply sloped Northeast amendment plot had the highest amount of organic matter applied along with lime, but neither the organic matter nor lime significantly changed pH, pCu nor uptake of copper into the plants. Vegetation cover of the Northeast reference plot decreased after being limed by the white rain (**Table 16a**), but recovered some after amendments were applied (**Table 16b**), possibly because of organic matter additions, as seen at the Morenci mine. This seems unlikely however, because Morenci mine's cover (Gila Conglomerate borrow material) was likely very low in total organic carbon (TOC), resulting in a dramatic response, whereas the amendment plot areas were not that low in TOC for a semi-arid soil. TOC of the Northeast reference plot was generally over 1percent (**Table 3**) and was not even significantly different from the amended plot indicating organic matter was unlikely to be responsible for the cover increase (**Figure 4b**, **Table 11**). Changes in the plant community (increase in cover of annual species, decreased grasses) of the Northeast amendment plot were more likely due to time since disturbance during amendment application as indicated by the CCA (**Table 13b**) showing that the greatest separation of Northeast plot community composition between treated and untreated plots is based on this disturbance variable (**Figure 13b**), not TOC or carbon to nitrogen ratio (C:N). However, soluble copper concentrations also separate the plot community changes over time. Soluble copper decreased as the plot community recovered from the treatment disturbance, which adds more uncertainty into the key drivers of changes on this plot, and whether organic matter caused the increase in soluble copper. If the manure increased soluble copper, the effect was negative (supported by loss of grass cover), opposite of the objective of the remedial technology.

Figure B-21-1. Relative biomass of plant life forms when treated with biosolids/wood waste (shown in tons/acre), showing no improvement relative to controls in perennial species when applied to topsoil (Paschke et al. 2005).



Weed seed embedded in manure often is a problem because it reduces the ability of perennial native species to establish. The weed seed in the organic matter (manure) applied may have contributed to weed invasion on the East and North amendment plots. However, the invaders naturally inhabit some areas in the STSIU and the impact of weed seed in the manure is uncertain. In contrast, weed seed appeared to be minimal on the Northeast amendment plot, given the early invaders were the shrubs of lote bush, rabbit thorn, false mesquite, whiteball acacia, and an increase in mesquite. The amended Northeast plot still lost the late successional grass species of sideoats grama and blue grama, which were relatively abundant before the white rain. This pattern of increased shrubs and loss of gramas is indicative of the plot being set back to an earlier successional stage (Bestelmeyer et al. 2004, **Appendix B-3**) by disturbance, not by organic matter applications.

Figure B-21-2. Canopy cover and richness were not considerably different from the control when manure was applied at different rates (Bay et al. 2010).

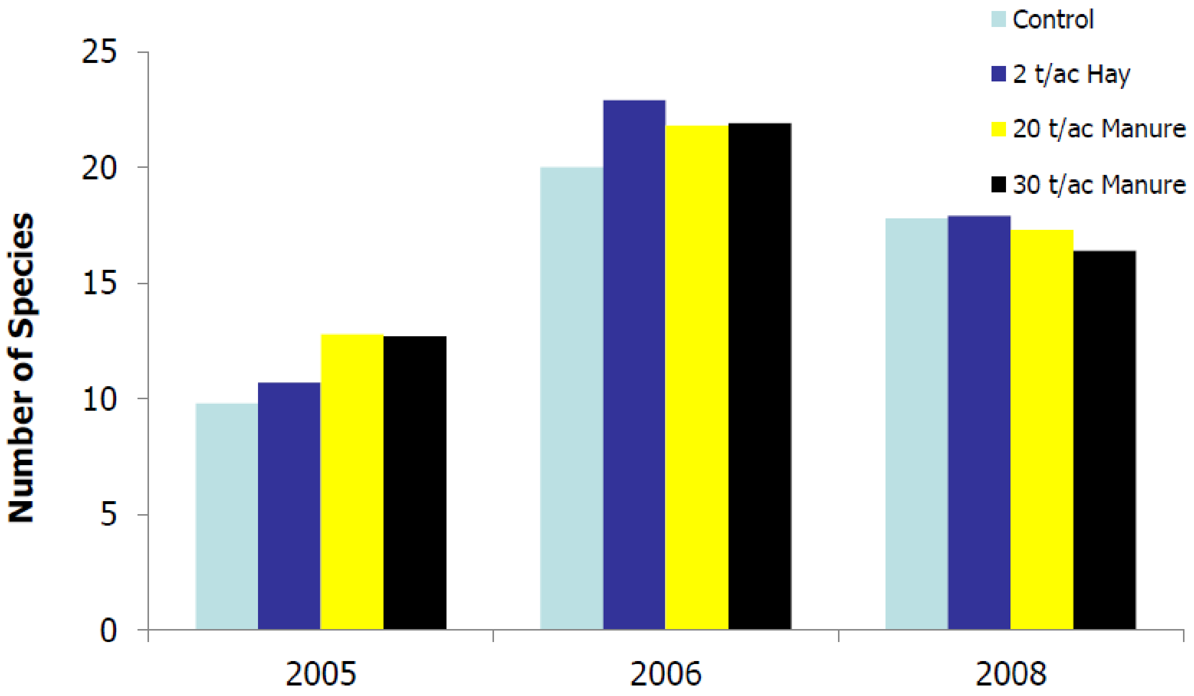


Photo 15. Morenci, low rate at 5 years

Photo 16. Morenci, intermediate rate at 5 years

Photo 17. Morenci, high rate at 5 years

Evidence is equivocal as to whether organic matter increased weedy species invasion on the North and East amendment plots. Organic matter can create a more favorable nutrient environment for the weeds to establish as well as introduce weed seed (Molles 2005). In contrast to the lower weed invasion in the Northeast amendment plot, the relatively flat North and East amendment plots with organic matter applied had TOC and more weedy annuals increase, annuals that were toxic to wildlife and cattle (golden crownbeard in East plot, carelessweed in North plot). The organic matter may have run downslope off the Northeast plot, sparing the plot from the weed invasion seen on the tilled plots and often seen in other study areas (Paschke et al. 2005, Ippolito et al 2010, Bay et al. 2010). The tilled haul road did not have a large amount of annual weedy species invading once Russian thistle died back after the first year, possibly because organic matter was not applied. Because annual weeds increased less on the plot that was not tilled but also less on the haul road that was tilled, other factors than tilling, possibly organic matter, may have increased undesirable weed invasion. However, only limited amounts of weed invasion occurred with (Northeast amendment plot) and without (haul road) organic matter applied, making this conclusion uncertain.

What is clear is that the rocky poor rangeland soils do not need organic matter, just tilling, to have high plant cover as shown by the haul road results. The fair rangeland plots also probably do not need organic matter as seen by the Northeast plot that did not exhibit a change in TOC, and the North amendment plot experienced a reduction in cover and degraded plant community after its application. Though the conclusion is tenuous, the weight of evidence suggests that organic matter is not very beneficial and possibly may do more harm than good to rangeland and wildlife habitat. It is not recommended as a remedial technology. **Table 20** summarizes the conclusions on the effect of organic matter application on plant communities. Additionally, **Table 20** summarizes these results and conclusions for all three technologies by presenting the apparent effectiveness of each separate technology on the primary metrics and final recommendations for use of each as a standalone treatment. As more information becomes available, these conclusions may be revised. The benefits of the combination of treatments and the information in this appendix is combined to develop the final conclusions in the main text.

Appendix B-22. Properties of the Canonical Correspondence Analysis

Overview of Canonical Correspondence Analysis Biplots

In this study, the Canonical Correspondence Analysis (CCA) acts to organize the sampling locations along numerous axes based on the relationship between their species composition, soil chemistry, and disturbance factor attributes. CCA axis 1 displays the maximum correlation between the sites and species. The remaining CCA axes display increasingly less correlation as additional axes are created. The majority of the variation in the data is displayed on the CCA axes 1 and 2; therefore, these axes are the only axes included in the results of this analysis. CCA axes are displayed on two biplots that show the distribution relative to environmental variables of (1) sampling events for each location and (2) individual species (**Figure 13a and Figure 13b**). The environmental parameters are added as vectors that show how the sampling events and the species are related to each soil chemistry and disturbance parameter.

Figure 13a

Figure 13a shows the biplots with all plots, including the West plots included. Both pCu (r^2 = 0.67, P = 0.001) and pH (r^2 = 0.66, P = 0.001) were most strongly correlated with the ordination, indicating that, of all the soil chemistry parameters measured, these two parameters accounted for most of the variation in species composition, whether the plot was amended or not. Copper concentration (r^2 = 0.41, P = 0.001) and soluble copper concentration (r^2 = 0.40, P = 0.002) are also correlated to the ordination, though not as strongly, and in an opposite direction of pCu and pH, as expected. Disturbance (most correlated to axis CCA1 because it is in the same direction) and tilling (binary variable represented by points [centroids] that fall along the diagonal axis at right angles to pH) are environmental variables also significantly correlated with the ordination in **Figure 13a** (r^2 = 0.42, P = 0.003 for disturbance; r^2 = 0.37, P = 0.001 for tilling).

As expected, the species in the non-West plots are associated with higher disturbance or tilling except during pre-amendment sampling events and during one East reference plot sampling event (**Figure 13a**). The post-treatment reference plots (D,E,F triangular symbols in **Figure 13a**) may have been influenced by the colonizers on the disturbed plots (or possibly were accidentally crushed by a vehicle), explaining why their plant communities are associated with a minor amount of disturbance when compared to their pre-treatment condition ("A" square symbol), though certainly less so than the amended plots. Note that the the West plots do not have an "A" plot because one of the chemical variables, copper, was not sampled in the first sampling event in May 2008.

Not surprisingly, tilling completely separates the plant community composition of the North and East amendment plots from their reference plots in **Figure 13a**. Total organic carbon (TOC) and carbon to nitrogen ratio (C:N) also tend to separate them (more TOC and lower C:N in treated plots), though they are not significantly correlated to the ordination ($P \geq 0.254$). Earliest successional communities occur right after tilling (indicated with letter B on biplot in **Figure 13a**) and are associated with high TOC and disturbance (near the ends of these arrows). On the untilled Northeast amendment plot, the early successional community composition (shown by B,C,D) is associated with high soluble copper. Later successional stages (E,F) are associated with lower concentrations of soluble copper and become more similar to the reference plot. Overall, the environmental variables accounted for 38 percent of the variation in species composition, meaning that 62 percent is explained by other factors (e.g., possibly rangeland condition, soil texture).

Figure 13b

When the two West control plots were removed from the analysis, as shown in **Figure 13b**, to only evaluate plots in the mesquite/grama alliance, 39 percent of the variation in species composition was explained by the environmental variables, similar to the biplots that included the West control plots in **Figure 13a**. The same general relationships between plot sampling events and environmental variables held except that TOC contributes significantly to separating amended and non-amended plots at the 90 percent confidence level ($r^2 = 0.25$, $P = 0.052$), and disturbance is almost as strongly related to the ordination as pCu and pH ($r^2 = 0.53$ vs. 0.60 for pCu and 0.54 for pH). The variable that best separates East and North amended plot communities from their untreated reference plots (**Figure 13b**) is TOC (higher TOC in plots with organic matter added). also separates them though less perfectly.

Soil pCu and pH (correlated with CCA1 axis) also tend to separate the amended and reference plot communities in the North plot (higher on amended plots) but less well for the East plot (**Figure 12b**) and neither separates these plots as well as TOC or tilling. For the Northeast plots, pH or pCu are not important for separating the treated and untreated plot. Also for the Northeast plots, time since disturbance (correlated with CCA2 axis and higher on amended plots) best separates communities of amended from untreated plots, and soluble copper is less important than when the West plots were included. The correlation with general disturbance was slightly stronger than the correlation with tilling alone ($r^2 = 0.53$, $P = 0.002$ versus $r^2 = 0.31$, $P = 0.001$, respectively).

Figure 13c

When the two West control plots were removed from the analysis and precipitation and season of the survey were included as environmental variables, as shown in **Figure 13c**, 46 percent of the variation in species composition was explained by the environmental variables, with relationships similar to the biplots without the West control plots that did not include season and precipitation (**Figure 13b**). Both season and precipitation were significantly correlated with the ordination at the 90 percent confidence level ($r^2 = 0.11$, $P = 0.064$ and $r^2 = 0.25$, $P = 0.055$, respectively) and had relationships with the ordination that were relatively similar to TOC (also significant at 90 percent confidence level, $r^2 = 0.20$, $P = 0.01$) and C:N (although non-significant, $P = 0.42$, and opposite of precipitation).

West Reference	U04-1024	AOC Background Report	May-95	1836	8.05	6.18

Notes:

1 -Copper data are from Arcadis (2017) white rain report, the table in Appendix E, where adjustments for sieving and depth of sample were made. This copper and the May/June 2008 pH value were used to calculate and capture pCu variability in these plots. See Figure A-16 for map of locations.

2 - pH sampled in adjacent reference plots (Appendix A-1) was combined with copper from the less collocated plots in this table to estimate pCu for the adjacent reference plots. When two less collocated plots are included (which represent variability), the 10 pH values in Appendix A-1 were split into two groups and averaged per group to obtain a value for each plot.

3 - Copper concentrations in red represent different geologic unit than amendment plot.

Appendix C-3
Surface Soil Analytical Values for Individual Samples on Amendment and Reference Plots

Year 5 Amendment Study Monitoring Report
Freeport-McMoRan Chino Mines Company
Vanadium, New Mexico

Sample Location	Sample Date	Soil Chemistry					
		pH[1] (s.u.)	Copper[1] (mg/kg)	TOC (%)	SPLP Copper (mg/L)[2]	pCu	Carbon: Nitrogen Ratio (X:1)
Organic Matter Amendment Composition [4]							
Pen # 1	4/10/2008	7.98	257	20	0.11	8.38	24.5
Pen # 2	4/10/2008	8.72	248	18	0.01	9.11	33.3

Notes:

s.u. = standard units

mg/kg = milligrams per kilogram

TOC = Total Organic Carbon

SPLP = Synthetic Precipitation Leaching Procedure

mg/L = milligrams per liter

nd = non-detect. Detection limit indicated in parentheses.

1 - All pH and total copper sample concentrations measured between 2006 and 2010 are adjusted to sieved (< 2mm) concentrations using a regression in text. Data from 2011 to 2013 were sieved to < 2mm in laboratory before analysis. The 10 field pH samples in May 2008 are shown in Appendix A-1.

2 - All SPLP Cu analyzed using modified 5:1 ratio with $CaCl_2$, except October 2011 to April 2013 used standard 1:20 ratio with DI water.

3- 2006 sample in East plot sampled near but not in amendment plot due to heavy truck traffic preventing access.

4 - In addition to copper, a suite of metals was tested on the organic matter in the field using XRF and all were below the detection limit.

Fall 2011 sample analysis was by ACZ Labs while all previous sample analysis was by ACZ.

Notes:

s.u. - standard units

mg/kg - milligrams per kilogram

TOC - Total Organic Carbon

SPLP - Synthetic Precipitation Leaching Procedure

mg/L - milligrams per liter

nd - non-detect. Detection limit indicated in parentheses.

1 - All pH and total copper sample concentrations measured between 2008 and 2010 shown here adjusted to sieved(< 2 mm) concentrations using a regression in text. Data from 2011 to 2013 were sieved to < 2mm in laboratory before analysis.

2 - All SPLP Cu analyzed using modified 5:1 ratio with $CaCl_2$, except October 2011 to April 2013 used standard 1:20 ratio with DI water.

Fall 2011 sample analysis was by ACZ Labs while all previous sample analysis was by ACZ. No subsurface samples taken in 2006.

Notes:

Surface samples collected in top 6 inches of soil profile. Subsurface samples collected in 6 inches above calliche layer (or if no caliche layer shallower than 24", then 18-24")

s.u. - standard units

mg/kg - milligrams per kilogram

TOC - Total Organic Carbon

SPLP - Synthetic Precipitation Leaching Procedure

mg/L - milligrams per liter

1 - All pH and total copper sample concentrations measured between 2008 and 2010 are shown adjusted to sieved (<2 mm) concentrations using a regression in text. 2011 to 2013 data were sieved to < 2 mm in laboratory.

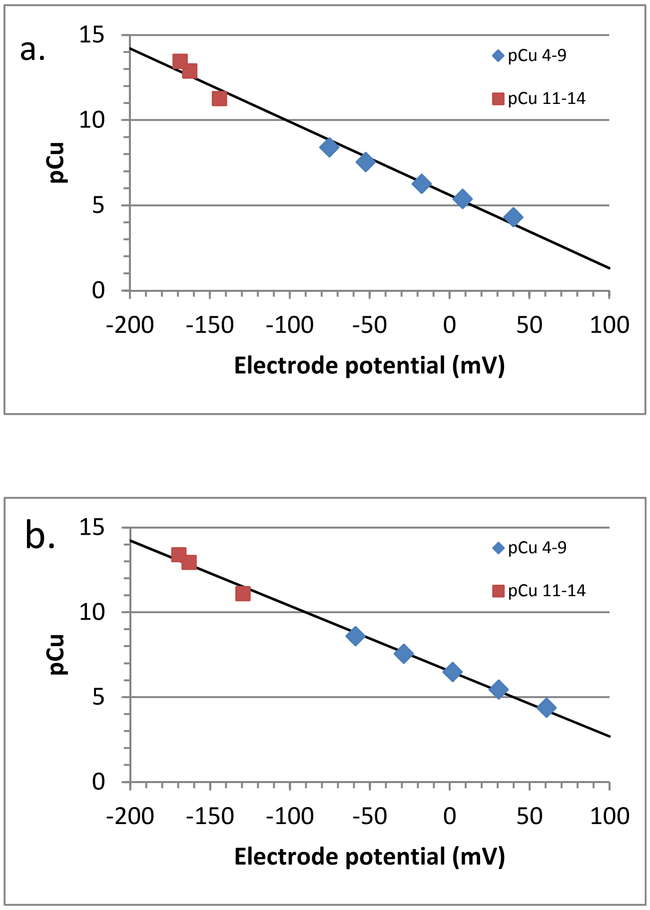
2 - All SPLP Cu analyzed using modified 5:1 ratio with $CaCl_2$, except October 2011 to April 2013 used standard 1:20 ratio with DI water.

No subsurface samples taken in 2006.

Appendix C-6: Measurement of pCu using Electrode Potentials

Energy labs measured pCu following protocols in Sauve et al. 1995. Specifically,

1. Measured pCu was calculated based on electrode potentials of soil solution.
2. The electrode was calibrated in $CaCl_2$ solutions of various known cupric ion activity solutions to develop a calibration curve between electrode potential in millivolts and cupric ion activity.
3. The calibration curve was used to estimate pCu from measured electrode potential.
4. Two curves were used on two different days for different batches of soil for the amendment study and the two regressions lines used are shown below in Figures A-6-1a and A-6-1b.



y = -0.043002x + 5.606284

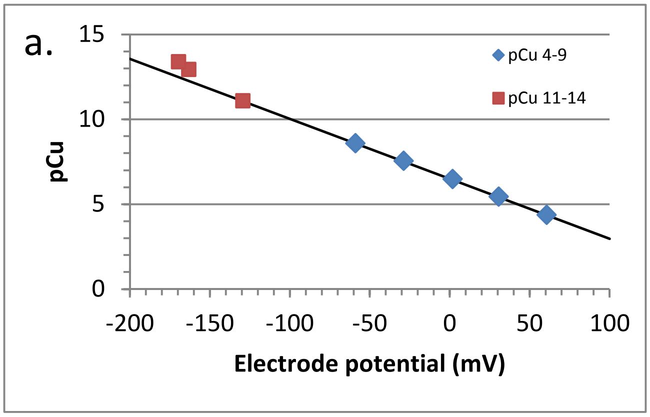
R^2 = 0.986 (all data)

y = -0.038467x + 6.521146

R^2 = 0.995 (all data)

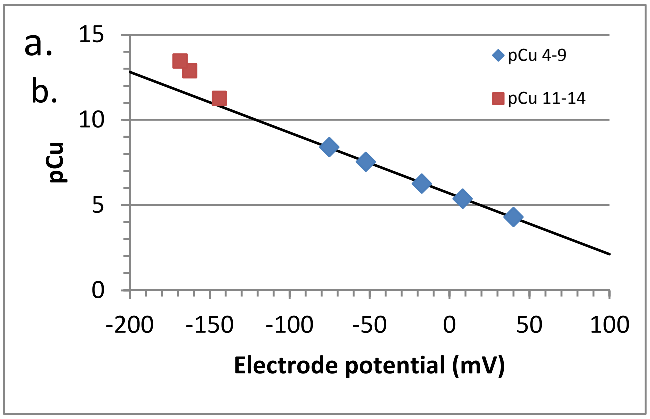
Figure A-6-1. Energy Laboratories pCu calibration data on (a) December 19, 2013 and (b) December 20, 2013.

Although Energy Laboratories used the same recipe for their Cu^{2+} calibration solution as Sauvé et al. (1995) used[1], the calibration data generated by Energy Laboratories were only linear between pCu values of approximately 4 and 9 (Figures A-6-2a and A-6-2b). Non-linearity also was observed in the calibration curves used in the sitewide ERA (Newfields 2005). At pCu values greater than 9, the plots of pCu *versus* electrode potential (as mV) curved upward from a straight line (Figures A-6-2a and A-6-2b). Alternatively, it is possible to fit a non-linear calibration curve, but the overall implications of a non-linear curve have yet to be evaluated and will be discussed in greater detail in the pending Phytotoxicity Report. As a compromise between fitting a line between 4 and 9 and a non-linear curve, Energy Laboratories used a linear calibration curve fit to all the calibration data (Figure A-6-1) to estimate pCu from measured electrode potential.



$y = -0.035318x + 6.502969$

$R^2 > 0.999$ (pCu 4-9 only)



$y = -0.035620x + 5.679377$

$R^2 = 0.999$ (pCu 4-9 only)

Figure A-6-2. Energy Laboratories pCu calibration data on (a) December 19, 2013 and (b) December 20, 2013.

---

[1] Calibration solution containing $Cu(NO_3)_2$, iminodiacetic acid, $KHC_8H_4O_4$, $CaCl_2$, and NaOH, with pH adjusted using HNO_3; see Electrode Calibration section on page 374 in Sauvé et al. 1995.

Notes:

1 - AGP is calculated from pyritic/sulfide sulfur where S(%)*31.25 = AGP. AGP was calculated using the detection limit when pyritic/sulfide sulfur was less than 0.01%.

AGP = acid generation potential
ANP = acid neutralization potential
NNP = Net Neutralization Potential
NPR = Neutralization Potential Ratio

Notes:

Surface samples collected in top 6 inches of soil profile. Subsurface samples collected in six inches above calliche layer. (or if no caliche layer shallower than 24", then 18-24")
s.u. - standard units
mg/kg - milligrams per kilogram
TOC - Total Organic Carbon
SPLP - Synthetic Precipitation Leaching Procedure
mg/L - milligrams per liter
nd - non-detect. Detection limit indicated in paratheses.
1 - Weighted average 0-1" and 2-4" samples to represent 0-4" sample

Organic Matter Amendment Composition[2]							
Pen # 1	4/10/2008	159,000	4,710	71.30	-	-	8,151
Pen # 2	4/10/2008	8,720	7,210	146.00	-	-	5,413

Notes:
s.u. - standard units
mg/kg - milligrams per kilogram
TOC - Total Organic Carbon
SPLP - Synthetic Precipitation Leaching Procedure
mg/L - milligrams per liter
nd - non-detect. Detection limit indicated in parentheses.
1 - TKN for the Oct 2011 sampling event was incorrectly analyzed by ACZ and was subsequently resubmitted to the original laboratory (Anatec) for this analysis even though the EPA's required hold time had been exceeded.
2 - In addition to copper, a suite of metals was tested on the organic matter in the field using XRF and all were below the detection limit.
Fall 2011 sample analysis was by ACZ Labs while all previous sample analysis was done by SVL

Lab Data

ACZ Laboratories, Inc.
2773 Downhill Drive Steamboat Springs, CO 80487 (800) 334-5493

Analytical Report

May 22, 2013

Report to:
Pam Pinson
Freeport-McMoRan - Chino Mines Company
PO Box 10
Bayard, NM 88023

Bill to:
Pam Pinson
Freeport-McMoRan - Chino Mines Company
P.O. Box 13308
Phoenix, AZ 85002-3308

cc: Matthew Barkley

Project ID: ZN000001M5
ACZ Project ID: L11766

Pam Pinson:

Enclosed are the analytical results for sample(s) submitted to ACZ Laboratories, Inc. (ACZ) on April 26, 2013. This project has been assigned to ACZ's project number, L11766. Please reference this number in all future inquiries.

All analyses were performed according to ACZ's Quality Assurance Plan. The enclosed results relate only to the samples received under L11766. Each section of this report has been reviewed and approved by the appropriate Laboratory Supervisor, or a qualified substitute.

Except as noted, the test results for the methods and parameters listed on ACZ's current NELAC certificate letter (#ACZ) meet all requirements of NELAC.

This report shall be used or copied only in its entirety. ACZ is not responsible for the consequences arising from the use of a partial report.

All samples and sub-samples associated with this project will be disposed of after June 21, 2013. If the samples are determined to be hazardous, additional charges apply for disposal (typically $11/sample). If you would like the samples to be held longer than ACZ's stated policy or to be returned, please contact your Project Manager or Customer Service Representative for further details and associated costs. ACZ retains analytical raw data reports for ten years.

If you have any questions or other needs, please contact your Project Manager.

S. Habermehl

Scott Habermehl has reviewed
and approved this report.

Inorganic Reference

Report Header Explanations

Batch	A distinct set of samples analyzed at a specific time
Found	Value of the QC Type of interest
Limit	Upper limit for RPD, in %.
Lower	Lower Recovery Limit, in % (except for LCSS, mg/Kg)
MDL	Method Detection Limit. Same as Minimum Reporting Limit. Allows for instrument and annual fluctuations.
PCN/SCN	A number assigned to reagents/standards to trace to the manufacturer's certificate of analysis
PQL	Practical Quantitation Limit, typically 5 times the MDL.
QC	True Value of the Control Sample or the amount added to the Spike
Rec	Recovered amount of the true value or spike added, in % (except for LCSS, mg/Kg)
RPD	Relative Percent Difference, calculation used for Duplicate QC Types
Upper	Upper Recovery Limit, in % (except for LCSS, mg/Kg)
Sample	Value of the Sample of interest

QC Sample Types

AS	Analytical Spike (Post Digestion)	*LCSWD*	Laboratory Control Sample - Water Duplicate
ASD	Analytical Spike (Post Digestion) Duplicate	*LFB*	Laboratory Fortified Blank
CCB	Continuing Calibration Blank	*LFM*	Laboratory Fortified Matrix
CCV	Continuing Calibration Verification standard	*LFMD*	Laboratory Fortified Matrix Duplicate
DUP	Sample Duplicate	*LRB*	Laboratory Reagent Blank
ICB	Initial Calibration Blank	*MS*	Matrix Spike
ICV	Initial Calibration Verification standard	*MSD*	Matrix Spike Duplicate
ICSAB	Inter-element Correction Standard - A plus B solutions	*PBS*	Prep Blank - Soil
LCSS	Laboratory Control Sample - Soil	*PBW*	Prep Blank - Water
LCSSD	Laboratory Control Sample - Soil Duplicate	*PQV*	Practical Quantitation Verification standard
LCSW	Laboratory Control Sample - Water	*SDL*	Serial Dilution

QC Sample Type Explanations

Blanks	Verifies that there is no or minimal contamination in the prep method or calibration procedure.
Control Samples	Verifies the accuracy of the method, including the prep procedure.
Duplicates	Verifies the precision of the instrument and/or method.
Spikes/Fortified Matrix	Determines sample matrix interferences, if any.
Standard	Verifies the validity of the calibration.

ACZ Qualifiers (Qual)

B	Analyte concentration detected at a value between MDL and PQL. The associated value is an estimated quantity.
H	Analysis exceeded method hold time. pH is a field test with an immediate hold time.
L	Target analyte response was below the laboratory defined negative threshold.
U	The material was analyzed for, but was not detected above the level of the associated value. The associated value is either the sample quantitation limit or the sample detection limit.

Method References

Comments

(1) QC results calculated from raw data. Results may vary slightly if the rounded values are used in the calculations.
(2) Soil, Sludge, and Plant matrices for Inorganic analyses are reported on a dry weight basis.
(3) Animal matrices for Inorganic analyses are reported on an "as received" basis.
(4) An asterisk in the "XQ" column indicates there is an extended qualifier and/or certification qualifier associated with the result.
(5) If the MDL equals the PQL or the MDL column is omitted, the PQL is the reporting limit.

For a complete list of ACZ's Extended Qualifiers, please click: http://www.acz.com/public/extquallist.pdf

No certification qualifiers associated with this analysis

Sample Receipt

Freeport-McMoRan - Chino Mines Company
ZN000001M5

ACZ Project ID: L11766
Date Received: 04/26/2013 09:54
Received By: gac
Date Printed: 5/22/2013

Receipt Verification

	YES	NO	NA
1) Is a foreign soil permit included for applicable samples?			X
2) Is the Chain of Custody or other directive shipping papers present?	X		
3) Does this project require special handling procedures such as CLP protocol?			X
4) Are any samples NRC licensable material?			X
5) If samples are received past hold time, proceed with requested short hold time analyses?	X		
6) Is the Chain of Custody complete and accurate?	X		
7) Were any changes made to the Chain of Custody prior to ACZ receiving the samples?	X		

`A change was made in the line 1 and 2 section prior to ACZ custody.`

Samples/Containers

	YES	NO	NA
8) Are all containers intact and with no leaks?	X		
9) Are all labels on containers and are they intact and legible?	X		
10) Do the sample labels and Chain of Custody match for Sample ID, Date, and Time?	X		
11) For preserved bottle types, was the pH checked and within limits?	X		
12) Is there sufficient sample volume to perform all requested work?	X		
13) Is the custody seal intact on all containers?			X
14) Are samples that require zero headspace acceptable?			X
15) Are all sample containers appropriate for analytical requirements?	X		
16) Is there an Hg-1631 trip blank present?			X
17) Is there a VOA trip blank present?			X
18) Were all samples received within hold time?	X

If sample(s) received past holding time (HT), or if insufficient HT remains to complete analysis before expiration, shall ACZ proceed with requested short HT analyses? YES ☒ NO ☐

If "NO" then ACZ will contact client for further instruction. If neither "YES" nor "NO" is indicated, ACZ will proceed with the requested analyses, even if HT is expired, and data will be qualified.

Are samples for CO DW Compliance Monitoring? YES ☐ NO ☒

If yes, please include state forms. Results will be reported to PQL.

REMARKS

Sieve all soil samples to <2 mm prior to analysis. Soil should be reported on a dry weight basis.
Methods:
pH - 9045C, Calcium - 6010B, Potassium - 6010B, Nitrogen - 350.1/353.2/351.4, Total Organic Carbon - 9060, Copper - Modified 1312 extraction, 3010A digestion, 6010B analysis

Please refer to ACZ's terms & conditions located on the reverse side of this COC.

ACZ Project ID: L11852

Pam Pinson:

Enclosed are the analytical results for sample(s) submitted to ACZ Laboratories, Inc. (ACZ) on May 01, 2013. This project has been assigned to ACZ's project number, L11852. Please reference this number in all future inquiries.

All analyses were performed according to ACZ's Quality Assurance Plan. The enclosed results relate only to the samples received under L11852. Each section of this report has been reviewed and approved by the appropriate Laboratory Supervisor, or a qualified substitute.

Except as noted, the test results for the methods and parameters listed on ACZ's current NELAC certificate letter (#ACZ) meet all requirements of NELAC.

This report shall be used or copied only in its entirety. ACZ is not responsible for the consequences arising from the use of a partial report.

All samples and sub-samples associated with this project will be disposed of after June 29, 2013. If the samples are determined to be hazardous, additional charges apply for disposal (typically $11/sample). If you would like the samples to be held longer than ACZ's stated policy or to be returned, please contact your Project Manager or Customer Service Representative for further details and associated costs. ACZ retains analytical raw data reports for ten years.

If you have any questions or other needs, please contact your Project Manager.

Inorganic Reference

Report Header Explanations

Batch	A distinct set of samples analyzed at a specific time
Found	Value of the QC Type of interest
Limit	Upper limit for RPD, in %.
Lower	Lower Recovery Limit, in % (except for LCSS, mg/Kg)
MDL	Method Detection Limit. Same as Minimum Reporting Limit. Allows for instrument and annual fluctuations.
PCN/SCN	A number assigned to reagents/standards to trace to the manufacturer's certificate of analysis
PQL	Practical Quantitation Limit, typically 5 times the MDL.
QC	True Value of the Control Sample or the amount added to the Spike
Rec	Recovered amount of the true value or spike added, in % (except for LCSS, mg/Kg)
RPD	Relative Percent Difference, calculation used for Duplicate QC Types
Upper	Upper Recovery Limit, in % (except for LCSS, mg/Kg)
Sample	Value of the Sample of interest

QC Sample Types

AS	Analytical Spike (Post Digestion)	*LCSWD*	Laboratory Control Sample - Water Duplicate
ASD	Analytical Spike (Post Digestion) Duplicate	*LFB*	Laboratory Fortified Blank
CCB	Continuing Calibration Blank	*LFM*	Laboratory Fortified Matrix
CCV	Continuing Calibration Verification standard	*LFMD*	Laboratory Fortified Matrix Duplicate
DUP	Sample Duplicate	*LRB*	Laboratory Reagent Blank
ICB	Initial Calibration Blank	*MS*	Matrix Spike
ICV	Initial Calibration Verification standard	*MSD*	Matrix Spike Duplicate
ICSAB	Inter-element Correction Standard - A plus B solutions	*PBS*	Prep Blank - Soil
LCSS	Laboratory Control Sample - Soil	*PBW*	Prep Blank - Water
LCSSD	Laboratory Control Sample - Soil Duplicate	*PQV*	Practical Quantitation Verification standard
LCSW	Laboratory Control Sample - Water	*SDL*	Serial Dilution

QC Sample Type Explanations

Blanks	Verifies that there is no or minimal contamination in the prep method or calibration procedure.
Control Samples	Verifies the accuracy of the method, including the prep procedure.
Duplicates	Verifies the precision of the instrument and/or method.
Spikes/Fortified Matrix	Determines sample matrix interferences, if any.
Standard	Verifies the validity of the calibration.

ACZ Qualifiers (Qual)

B	Analyte concentration detected at a value between MDL and PQL. The associated value is an estimated quantity.
H	Analysis exceeded method hold time. pH is a field test with an immediate hold time.
L	Target analyte response was below the laboratory defined negative threshold.
U	The material was analyzed for, but was not detected above the level of the associated value. The associated value is either the sample quantitation limit or the sample detection limit.

Method References

Comments

(1) QC results calculated from raw data. Results may vary slightly if the rounded values are used in the calculations.
(2) Soil, Sludge, and Plant matrices for Inorganic analyses are reported on a dry weight basis.
(3) Animal matrices for Inorganic analyses are reported on an "as received" basis.
(4) An asterisk in the "XQ" column indicates there is an extended qualifier and/or certification qualifier associated with the result.
(5) If the MDL equals the PQL or the MDL column is omitted, the PQL is the reporting limit.

Inorganic Extended Qualifier Report

Freeport-McMoRan - Chino Mines Company ACZ Project ID: ***L11852***

ACZ ID	WORKNUM	PARAMETER	METHOD	QUAL	DESCRIPTION
L11852-01	WG343429	Calcium, total (3050)	M6010B ICP	MA	Recovery for either the spike or spike duplicate was outside of the acceptance limits; the RPD was within the acceptance limits.
		Copper, total (3050)	M6010B ICP	M3	The spike recovery value is unusable since the analyte concentration in the sample is disproportionate to the spike level. The recovery of the associated control sample (LCS or LFB) was acceptable.
	WG343483	Carbon, total (TC)	ASA No.9 29-2.2.4 Combustion/IR	Q6	Sample was received above recommended temperature.
		Carbon, total organic (TOC)	ASA No.9 29-2.2.4 Combustion/IR	Q6	Sample was received above recommended temperature.
			ASA No.9 29-2.2.4 Combustion/IR	ZQ	Analyte was not evaluated in the laboratory control standard. Either the analyte is not included in the scope of the analytical method or a commercial standard containing the analyte is not available.
	WG343695	Nitrate/Nitrite as N, soluble (Water)	M353.2 - Automated Cadmium Reduction	D1	Sample required dilution due to matrix.
			M353.2 - Automated Cadmium Reduction	HD	Analysis is outside the intended scope of the method, which does not provide hold time information for soil extracts. No hold time is observed for collection to extraction. The referenced method hold time is observed for extraction-to-analysis.
		Nitrite as N, soluble (Water)	M353.2 - Automated Cadmium Reduction	D1	Sample required dilution due to matrix.
			M353.2 - Automated Cadmium Reduction	HD	Analysis is outside the intended scope of the method, which does not provide hold time information for soil extracts. No hold time is observed for collection to extraction. The referenced method hold time is observed for extraction-to-analysis.
			M353.2 - Automated Cadmium Reduction	M2	Matrix spike recovery was low, the recovery of the associated control sample (LCS or LFB) was acceptable.
			M353.2 - Automated Cadmium Reduction	RA	Relative Percent Difference (RPD) was not used for data validation because the sample concentration is too low for accurate evaluation (< 10x MDL).
	WG343700	Nitrogen, ammonia (Water)	M350.1 - Automated Phenate	D1	Sample required dilution due to matrix.
			M350.1 - Automated Phenate	HD	Analysis is outside the intended scope of the method, which does not provide hold time information for soil extracts. No hold time is observed for collection to extraction. The referenced method hold time is observed for extraction-to-analysis.
			M350.1 - Automated Phenate	RA	Relative Percent Difference (RPD) was not used for data validation because the sample concentration is too low for accurate evaluation (< 10x MDL).
	WG343775	Nitrogen, total Kjeldahl	M351.2 - TKN by Block Digester	M2	Matrix spike recovery was low, the recovery of the associated control sample (LCS or LFB) was acceptable.
			M351.2 - TKN by Block Digester	Q6	Sample was received above recommended temperature.

Soil Analysis

The following parameters are not offered for certification or are not covered by NELAC certificate #ACZ.

Carbon, total (TC)	ASA No.9 29-2.2.4 Combustion/IR
Carbon, total organic (TOC)	ASA No.9 29-2.2.4 Combustion/IR
pH, Saturated Paste	EPA 600/2-78-054, section 3.2.2
Solids, Percent	CLPSOW390, PART F, D-98

Wet Chemistry

The following parameters are not offered for certification or are not covered by NELAC certificate #ACZ.

Nitrate/Nitrite as N, soluble (Water)	M353.2 - Automated Cadmium Reduction
Nitrite as N, soluble (Water)	M353.2 - Automated Cadmium Reduction
Nitrogen, ammonia (Water)	M350.1 - Automated Phenate
Nitrogen, total Kjeldahl	M351.2 - TKN by Block Digester

Date Received: 05/01/2013 08:52
Received By: ksj
Date Printed: 5/22/2013

Receipt Verification

	YES	NO	NA
1) Is a foreign soil permit included for applicable samples?			X
2) Is the Chain of Custody or other directive shipping papers present?	X		▨
3) Does this project require special handling procedures such as CLP protocol?			X
4) Are any samples NRC licensable material?			X
5) If samples are received past hold time, proceed with requested short hold time analyses?	X		
6) Is the Chain of Custody complete and accurate?	X		▨
7) Were any changes made to the Chain of Custody prior to ACZ receiving the samples?	X		▨

A change was made in the date/time page 2 section prior to ACZ custody.

Samples/Containers

	YES	NO	NA
8) Are all containers intact and with no leaks?	X		▨
9) Are all labels on containers and are they intact and legible?	X		▨
10) Do the sample labels and Chain of Custody match for Sample ID, Date, and Time?	X		▨
11) For preserved bottle types, was the pH checked and within limits?			X
12) Is there sufficient sample volume to perform all requested work?	X		▨
13) Is the custody seal intact on all containers?			X
14) Are samples that require zero headspace acceptable?			X
15) Are all sample containers appropriate for analytical requirements?	X		▨
16) Is there an Hg-1631 trip blank present?			X
17) Is there a VOA trip blank present?			X
18) Were all samples received within hold time?	X		▨

Analytical Report

May 22, 2013

Report to:	Bill to:
Pam Pinson	Pam Pinson
Freeport-McMoRan - Chino Mines Company	Freeport-McMoRan - Chino Mines Company
PO Box 10	P.O. Box 13308
Bayard, NM 88023	Phoenix, AZ 85002-3308

cc: Matthew Barkley

Project ID: ZN000001M5
ACZ Project ID: L11853

Pam Pinson:

Enclosed are the analytical results for sample(s) submitted to ACZ Laboratories, Inc. (ACZ) on May 01, 2013. This project has been assigned to ACZ's project number, L11853. Please reference this number in all future inquiries.

All analyses were performed according to ACZ's Quality Assurance Plan. The enclosed results relate only to the samples received under L11853. Each section of this report has been reviewed and approved by the appropriate Laboratory Supervisor, or a qualified substitute.

Except as noted, the test results for the methods and parameters listed on ACZ's current NELAC certificate letter (#ACZ) meet all requirements of NELAC.

This report shall be used or copied only in its entirety. ACZ is not responsible for the consequences arising from the use of a partial report.

All samples and sub-samples associated with this project will be disposed of after June 21, 2013. If the samples are determined to be hazardous, additional charges apply for disposal (typically $11/sample). If you would like the samples to be held longer than ACZ's stated policy or to be returned, please contact your Project Manager or Customer Service Representative for further details and associated costs. ACZ retains analytical raw data reports for ten years.

If you have any questions or other needs, please contact your Project Manager.

Inorganic Reference

Report Header Explanations

Batch	A distinct set of samples analyzed at a specific time
Found	Value of the QC Type of interest
Limit	Upper limit for RPD, in %.
Lower	Lower Recovery Limit, in % (except for LCSS, mg/Kg)
MDL	Method Detection Limit. Same as Minimum Reporting Limit. Allows for instrument and annual fluctuations.
PCN/SCN	A number assigned to reagents/standards to trace to the manufacturer's certificate of analysis
PQL	Practical Quantitation Limit, typically 5 times the MDL.
QC	True Value of the Control Sample or the amount added to the Spike
Rec	Recovered amount of the true value or spike added, in % (except for LCSS, mg/Kg)
RPD	Relative Percent Difference, calculation used for Duplicate QC Types
Upper	Upper Recovery Limit, in % (except for LCSS, mg/Kg)
Sample	Value of the Sample of interest

QC Sample Types

AS	Analytical Spike (Post Digestion)	*LCSWD*	Laboratory Control Sample - Water Duplicate
ASD	Analytical Spike (Post Digestion) Duplicate	*LFB*	Laboratory Fortified Blank
CCB	Continuing Calibration Blank	*LFM*	Laboratory Fortified Matrix
CCV	Continuing Calibration Verification standard	*LFMD*	Laboratory Fortified Matrix Duplicate
DUP	Sample Duplicate	*LRB*	Laboratory Reagent Blank
ICB	Initial Calibration Blank	*MS*	Matrix Spike
ICV	Initial Calibration Verification standard	*MSD*	Matrix Spike Duplicate
ICSAB	Inter-element Correction Standard - A plus B solutions	*PBS*	Prep Blank - Soil
LCSS	Laboratory Control Sample - Soil	*PBW*	Prep Blank - Water
LCSSD	Laboratory Control Sample - Soil Duplicate	*PQV*	Practical Quantitation Verification standard
LCSW	Laboratory Control Sample - Water	*SDL*	Serial Dilution

QC Sample Type Explanations

Blanks	Verifies that there is no or minimal contamination in the prep method or calibration procedure.
Control Samples	Verifies the accuracy of the method, including the prep procedure.
Duplicates	Verifies the precision of the instrument and/or method.
Spikes/Fortified Matrix	Determines sample matrix interferences, if any.
Standard	Verifies the validity of the calibration.

ACZ Qualifiers (Qual)

B	Analyte concentration detected at a value between MDL and PQL. The associated value is an estimated quantity.
H	Analysis exceeded method hold time. pH is a field test with an immediate hold time.
L	Target analyte response was below the laboratory defined negative threshold.
U	The material was analyzed for, but was not detected above the level of the associated value. The associated value is either the sample quantitation limit or the sample detection limit.

Method References

Comments

(1) QC results calculated from raw data. Results may vary slightly if the rounded values are used in the calculations.
(2) Soil, Sludge, and Plant matrices for Inorganic analyses are reported on a dry weight basis.
(3) Animal matrices for Inorganic analyses are reported on an "as received" basis.
(4) An asterisk in the "XQ" column indicates there is an extended qualifier and/or certification qualifier associated with the result.
(5) If the MDL equals the PQL or the MDL column is omitted, the PQL is the reporting limit.

ACZ Project ID: L11853
Date Received: 05/01/2013 09:06
Received By: ksj
Date Printed: 5/22/2013

Receipt Verification

	YES	NO	NA
1) Is a foreign soil permit included for applicable samples?			X
2) Is the Chain of Custody or other directive shipping papers present?	X		▨
3) Does this project require special handling procedures such as CLP protocol?			X
4) Are any samples NRC licensable material?			X
5) If samples are received past hold time, proceed with requested short hold time analyses?	X		
6) Is the Chain of Custody complete and accurate?	X		▨
7) Were any changes made to the Chain of Custody prior to ACZ receiving the samples?	X		▨

`A change was made in the date/time page 1 and 2 section prior to ACZ custody.`

Samples/Containers

	YES	NO	NA
8) Are all containers intact and with no leaks?	X		▨
9) Are all labels on containers and are they intact and legible?	X		▨
10) Do the sample labels and Chain of Custody match for Sample ID, Date, and Time?	X		▨
11) For preserved bottle types, was the pH checked and within limits?			X
12) Is there sufficient sample volume to perform all requested work?	X		▨
13) Is the custody seal intact on all containers?			X
14) Are samples that require zero headspace acceptable?			X
15) Are all sample containers appropriate for analytical requirements?	X		▨
16) Is there an Hg-1631 trip blank present?			X
17) Is there a VOA trip blank present?			X
18) Were all samples received within hold time?	X		▨

cc: Matthew Barkley

Project ID: ZN000001M5
ACZ Project ID: L11854

Pam Pinson:

Enclosed are the analytical results for sample(s) submitted to ACZ Laboratories, Inc. (ACZ) on May 01, 2013. This project has been assigned to ACZ's project number, L11854. Please reference this number in all future inquiries.

All analyses were performed according to ACZ's Quality Assurance Plan. The enclosed results relate only to the samples received under L11854. Each section of this report has been reviewed and approved by the appropriate Laboratory Supervisor, or a qualified substitute.

Except as noted, the test results for the methods and parameters listed on ACZ's current NELAC certificate letter (#ACZ) meet all requirements of NELAC.

This report shall be used or copied only in its entirety. ACZ is not responsible for the consequences arising from the use of a partial report.

All samples and sub-samples associated with this project will be disposed of after June 29, 2013. If the samples are determined to be hazardous, additional charges apply for disposal (typically $11/sample). If you would like the samples to be held longer than ACZ's stated policy or to be returned, please contact your Project Manager or Customer Service Representative for further details and associated costs. ACZ retains analytical raw data reports for ten years.

If you have any questions or other needs, please contact your Project Manager.

Inorganic Reference

Report Header Explanations

Batch	A distinct set of samples analyzed at a specific time
Found	Value of the QC Type of interest
Limit	Upper limit for RPD, in %.
Lower	Lower Recovery Limit, in % (except for LCSS, mg/Kg)
MDL	Method Detection Limit. Same as Minimum Reporting Limit. Allows for instrument and annual fluctuations.
PCN/SCN	A number assigned to reagents/standards to trace to the manufacturer's certificate of analysis
PQL	Practical Quantitation Limit, typically 5 times the MDL.
QC	True Value of the Control Sample or the amount added to the Spike
Rec	Recovered amount of the true value or spike added, in % (except for LCSS, mg/Kg)
RPD	Relative Percent Difference, calculation used for Duplicate QC Types
Upper	Upper Recovery Limit, in % (except for LCSS, mg/Kg)
Sample	Value of the Sample of interest

QC Sample Types

AS	Analytical Spike (Post Digestion)	*LCSWD*	Laboratory Control Sample - Water Duplicate
ASD	Analytical Spike (Post Digestion) Duplicate	*LFB*	Laboratory Fortified Blank
CCB	Continuing Calibration Blank	*LFM*	Laboratory Fortified Matrix
CCV	Continuing Calibration Verification standard	*LFMD*	Laboratory Fortified Matrix Duplicate
DUP	Sample Duplicate	*LRB*	Laboratory Reagent Blank
ICB	Initial Calibration Blank	*MS*	Matrix Spike
ICV	Initial Calibration Verification standard	*MSD*	Matrix Spike Duplicate
ICSAB	Inter-element Correction Standard - A plus B solutions	*PBS*	Prep Blank - Soil
LCSS	Laboratory Control Sample - Soil	*PBW*	Prep Blank - Water
LCSSD	Laboratory Control Sample - Soil Duplicate	*PQV*	Practical Quantitation Verification standard
LCSW	Laboratory Control Sample - Water	*SDL*	Serial Dilution

QC Sample Type Explanations

Blanks	Verifies that there is no or minimal contamination in the prep method or calibration procedure.
Control Samples	Verifies the accuracy of the method, including the prep procedure.
Duplicates	Verifies the precision of the instrument and/or method.
Spikes/Fortified Matrix	Determines sample matrix interferences, if any.
Standard	Verifies the validity of the calibration.

ACZ Qualifiers (Qual)

B	Analyte concentration detected at a value between MDL and PQL. The associated value is an estimated quantity.
H	Analysis exceeded method hold time. pH is a field test with an immediate hold time.
L	Target analyte response was below the laboratory defined negative threshold.
U	The material was analyzed for, but was not detected above the level of the associated value. The associated value is either the sample quantitation limit or the sample detection limit.

Method References

(2) EPA 600/R-93-100. Methods for the Determination of Inorganic Substances in Environmental Samples, August 1993.
(3) EPA 600/R-94-111. Methods for the Determination of Metals in Environmental Samples - Supplement I, May 1994.
(4) EPA SW-846. Test Methods for Evaluating Solid Waste.
(5) Standard Methods for the Examination of Water and Wastewater.

Comments

(1) QC results calculated from raw data. Results may vary slightly if the rounded values are used in the calculations.
(2) Soil, Sludge, and Plant matrices for Inorganic analyses are reported on a dry weight basis.
(3) Animal matrices for Inorganic analyses are reported on an "as received" basis.
(4) An asterisk in the "XQ" column indicates there is an extended qualifier and/or certification qualifier associated with the result.
(5) If the MDL equals the PQL or the MDL column is omitted, the PQL is the reporting limit.

Soil Analysis

The following parameters are not offered for certification or are not covered by NELAC certificate #ACZ.

Carbon, total (TC)	ASA No.9 29-2.2.4 Combustion/IR
Carbon, total organic (TOC)	ASA No.9 29-2.2.4 Combustion/IR
pH, Saturated Paste	EPA 600/2-78-054, section 3.2.2
Solids, Percent	CLPSOW390, PART F, D-98

Wet Chemistry

The following parameters are not offered for certification or are not covered by NELAC certificate #ACZ.

Nitrate/Nitrite as N, soluble (Water)	M353.2 - Automated Cadmium Reduction
Nitrite as N, soluble (Water)	M353.2 - Automated Cadmium Reduction
Nitrogen, ammonia (Water)	M350.1 - Automated Phenate
Nitrogen, total Kjeldahl	M351.2 - TKN by Block Digester

ACZ Laboratories, Inc.

Sample Receipt

Freeport-McMoRan - Chino Mines Company
ZN000001M5

ACZ Project ID: L11854
Date Received: 05/01/2013 08:52
Received By: ksj
Date Printed: 5/22/2013

Receipt Verification

	YES	NO	NA
1) Is a foreign soil permit included for applicable samples?			X
2) Is the Chain of Custody or other directive shipping papers present?	X		▨
3) Does this project require special handling procedures such as CLP protocol?			X
4) Are any samples NRC licensable material?			X
5) If samples are received past hold time, proceed with requested short hold time analyses?	X		
6) Is the Chain of Custody complete and accurate?	X		▨
7) Were any changes made to the Chain of Custody prior to ACZ receiving the samples?	X		▨

`A change was made in the date/time page 1 section prior to ACZ custody.`

Samples/Containers

	YES	NO	NA
8) Are all containers intact and with no leaks?	X		▨
9) Are all labels on containers and are they intact and legible?	X		▨
10) Do the sample labels and Chain of Custody match for Sample ID, Date, and Time?	X		▨
11) For preserved bottle types, was the pH checked and within limits?			X
12) Is there sufficient sample volume to perform all requested work?	X		▨
13) Is the custody seal intact on all containers?			X
14) Are samples that require zero headspace acceptable?			X
15) Are all sample containers appropriate for analytical requirements?	X		▨
16) Is there an Hg-1631 trip blank present?			X
17) Is there a VOA trip blank present?			X
18) Were all samples received within hold time?	X		▨

If sample(s) received past holding time (HT), or if insufficient HT remains to complete analysis before expiration, shall ACZ proceed with requested short HT analyses? YES ☒ NO ☐
If "NO" then ACZ will contact client for further instruction. If neither "YES" nor "NO" is indicated, ACZ will proceed with the requested analyses, even if HT is expired, and data will be qualified.

Are samples for CO DW Compliance Monitoring? YES ☐ NO ☒
If yes, please include state forms. Results will be reported to PQL.

PROJECT INFORMATION

Quote #:
Project/PO #:
Reporting state for compliance testing:
Sampler's Name: Matt Bauer
Are any samples NRC licensable material? Yes No

ANALYSES REQUESTED (attach list or use quote number)

REMARKS

Sieve all soil samples to <2 mm prior to analysis. Soil should be reported on a dry weight basis.
Methods:
pH - 9045C, Calcium - 6010B, Potassium - 6010B, Nitrogen - 350.1/353.2/351.4, Total Organic Carbon - 9060, Copper - Modified 1312 extraction, 3010A digestion, 6010B analysis

Please refer to ACZ's terms & conditions located on the reverse side of this COC.

Analytical Report

May 30, 2013

Report to:
Pam Pinson
Freeport-McMoRan - Chino Mines Company
PO Box 10
Bayard, NM 88023

Bill to:
Pam Pinson
Freeport-McMoRan - Chino Mines Company
P.O. Box 13308
Phoenix, AZ 85002-3308

cc: Matthew Barkley

Project ID: ZN000001M5
ACZ Project ID: L11855

Pam Pinson:

Enclosed are the analytical results for sample(s) submitted to ACZ Laboratories, Inc. (ACZ) on May 01, 2013. This project has been assigned to ACZ's project number, L11855. Please reference this number in all future inquiries.

All analyses were performed according to ACZ's Quality Assurance Plan. The enclosed results relate only to the samples received under L11855. Each section of this report has been reviewed and approved by the appropriate Laboratory Supervisor, or a qualified substitute.

Except as noted, the test results for the methods and parameters listed on ACZ's current NELAC certificate letter (#ACZ) meet all requirements of NELAC.

This report shall be used or copied only in its entirety. ACZ is not responsible for the consequences arising from the use of a partial report.

All samples and sub-samples associated with this project will be disposed of after June 29, 2013. If the samples are determined to be hazardous, additional charges apply for disposal (typically $11/sample). If you would like the samples to be held longer than ACZ's stated policy or to be returned, please contact your Project Manager or Customer Service Representative for further details and associated costs. ACZ retains analytical raw data reports for ten years.

If you have any questions or other needs, please contact your Project Manager.

S. Habermehl

Inorganic Reference

Report Header Explanations

Batch	A distinct set of samples analyzed at a specific time
Found	Value of the QC Type of interest
Limit	Upper limit for RPD, in %.
Lower	Lower Recovery Limit, in % (except for LCSS, mg/Kg)
MDL	Method Detection Limit. Same as Minimum Reporting Limit. Allows for instrument and annual fluctuations.
PCN/SCN	A number assigned to reagents/standards to trace to the manufacturer's certificate of analysis
PQL	Practical Quantitation Limit, typically 5 times the MDL.
QC	True Value of the Control Sample or the amount added to the Spike
Rec	Recovered amount of the true value or spike added, in % (except for LCSS, mg/Kg)
RPD	Relative Percent Difference, calculation used for Duplicate QC Types
Upper	Upper Recovery Limit, in % (except for LCSS, mg/Kg)
Sample	Value of the Sample of interest

QC Sample Types

AS	Analytical Spike (Post Digestion)	*LCSWD*	Laboratory Control Sample - Water Duplicate
ASD	Analytical Spike (Post Digestion) Duplicate	*LFB*	Laboratory Fortified Blank
CCB	Continuing Calibration Blank	*LFM*	Laboratory Fortified Matrix
CCV	Continuing Calibration Verification standard	*LFMD*	Laboratory Fortified Matrix Duplicate
DUP	Sample Duplicate	*LRB*	Laboratory Reagent Blank
ICB	Initial Calibration Blank	*MS*	Matrix Spike
ICV	Initial Calibration Verification standard	*MSD*	Matrix Spike Duplicate
ICSAB	Inter-element Correction Standard - A plus B solutions	*PBS*	Prep Blank - Soil
LCSS	Laboratory Control Sample - Soil	*PBW*	Prep Blank - Water
LCSSD	Laboratory Control Sample - Soil Duplicate	*PQV*	Practical Quantitation Verification standard
LCSW	Laboratory Control Sample - Water	*SDL*	Serial Dilution

QC Sample Type Explanations

Blanks	Verifies that there is no or minimal contamination in the prep method or calibration procedure.
Control Samples	Verifies the accuracy of the method, including the prep procedure.
Duplicates	Verifies the precision of the instrument and/or method.
Spikes/Fortified Matrix	Determines sample matrix interferences, if any.
Standard	Verifies the validity of the calibration.

ACZ Qualifiers (Qual)

B	Analyte concentration detected at a value between MDL and PQL. The associated value is an estimated quantity.
H	Analysis exceeded method hold time. pH is a field test with an immediate hold time.
L	Target analyte response was below the laboratory defined negative threshold.
U	The material was analyzed for, but was not detected above the level of the associated value. The associated value is either the sample quantitation limit or the sample detection limit.

Method References

Comments

(1) QC results calculated from raw data. Results may vary slightly if the rounded values are used in the calculations.
(2) Soil, Sludge, and Plant matrices for Inorganic analyses are reported on a dry weight basis.
(3) Animal matrices for Inorganic analyses are reported on an "as received" basis.
(4) An asterisk in the "XQ" column indicates there is an extended qualifier and/or certification qualifier associated with the result.
(5) If the MDL equals the PQL or the MDL column is omitted, the PQL is the reporting limit.

For a complete list of ACZ's Extended Qualifiers, please click: http://www.acz.com/public/extquallist.pdf

Soil Analysis

The following parameters are not offered for certification or are not covered by NELAC certificate #ACZ.

Carbon, total (TC)	ASA No.9 29-2.2.4 Combustion/IR
Carbon, total organic (TOC)	ASA No.9 29-2.2.4 Combustion/IR
pH, Saturated Paste	EPA 600/2-78-054, section 3.2.2
Solids, Percent	CLPSOW390, PART F, D-98

Wet Chemistry

The following parameters are not offered for certification or are not covered by NELAC certificate #ACZ.

Nitrate/Nitrite as N, soluble (Water)	M353.2 - Automated Cadmium Reduction
Nitrite as N, soluble (Water)	M353.2 - Automated Cadmium Reduction
Nitrogen, ammonia (Water)	M350.1 - Automated Phenate
Nitrogen, total Kjeldahl	M351.2 - TKN by Block Digester

ACZ Laboratories, Inc.
2773 Downhill Drive Steamboat Springs, CO 80487 (800) 334-5493

Sample Receipt

Freeport-McMoRan - Chino Mines Company
ZN000001M5

ACZ Project ID: L11855
Date Received: 05/01/2013 09:00
Received By: ksj
Date Printed: 5/22/2013

Receipt Verification

	YES	NO	NA
1) Is a foreign soil permit included for applicable samples?			X
2) Is the Chain of Custody or other directive shipping papers present?	X		
3) Does this project require special handling procedures such as CLP protocol?			X
4) Are any samples NRC licensable material?			X
5) If samples are received past hold time, proceed with requested short hold time analyses?	X		
6) Is the Chain of Custody complete and accurate?	X		
7) Were any changes made to the Chain of Custody prior to ACZ receiving the samples?	X		

`A change was made in the date/time section prior to ACZ custody.`

Samples/Containers

	YES	NO	NA
8) Are all containers intact and with no leaks?	X		
9) Are all labels on containers and are they intact and legible?	X		
10) Do the sample labels and Chain of Custody match for Sample ID, Date, and Time?	X		
11) For preserved bottle types, was the pH checked and within limits?			X
12) Is there sufficient sample volume to perform all requested work?	X		
13) Is the custody seal intact on all containers?			X
14) Are samples that require zero headspace acceptable?			X
15) Are all sample containers appropriate for analytical requirements?	X		
16) Is there an Hg-1631 trip blank present?			X
17) Is there a VOA trip blank present?			X
18) Were all samples received within hold time?	X		

Chain of Custody Related Remarks

Client Contact Remarks

Shipping Containers

Cooler Id	Temp (°C)	Rad (µR/Hr)	Custody Seal Intact?
2599	11.8	16	Yes
2932	11.9	14	Yes
3076	11.7	16	Yes
3176	8.9	12	Yes

Client must contact an ACZ Project Manager if analysis should not proceed for samples received outside of their thermal preservation acceptance criteria.

sample(s) received past holding time (HT), or if insufficient HT remains to complete nalysis before expiration, shall ACZ proceed with requested short HT analyses? YES ☒ NO ☐
"NO" then ACZ will contact client for further instruction. If neither "YES" nor "NO" indicated, ACZ will proceed with the requested analyses, even if HT is expired, and data will be qualified.

re samples for CO DW Compliance Monitoring? YES ☐ NO ☒
yes, please include state forms. Results will be reported to PQL.

REMARKS

Sieve all soil samples to <2 mm prior to analysis. Soil should be reported on a dry weight basis.
Methods:
pH - 9045C, Calcium - 6010B, Potassium - 6010B, Nitrogen - 350.1/353.2/351.4, Total Organic Carbon - 9060, Copper - Modified 1312 extraction, 3010A digestion, 6010B analysis

Please refer to ACZ's terms & conditions located on the reverse side of this COC.

Analytical Report

May 30, 2013

Report to:	Bill to:
Pam Pinson	Pam Pinson
Freeport-McMoRan - Chino Mines Company	Freeport-McMoRan - Chino Mines Company
PO Box 10	P.O. Box 13308
Bayard, NM 88023	Phoenix, AZ 85002-3308

cc: Matthew Barkley

Project ID: ZN000001M5
ACZ Project ID: L11856

Pam Pinson:

Enclosed are the analytical results for sample(s) submitted to ACZ Laboratories, Inc. (ACZ) on May 01, 2013. This project has been assigned to ACZ's project number, L11856. Please reference this number in all future inquiries.

All analyses were performed according to ACZ's Quality Assurance Plan. The enclosed results relate only to the samples received under L11856. Each section of this report has been reviewed and approved by the appropriate Laboratory Supervisor, or a qualified substitute.

Except as noted, the test results for the methods and parameters listed on ACZ's current NELAC certificate letter (#ACZ) meet all requirements of NELAC.

This report shall be used or copied only in its entirety. ACZ is not responsible for the consequences arising from the use of a partial report.

All samples and sub-samples associated with this project will be disposed of after June 29, 2013. If the samples are determined to be hazardous, additional charges apply for disposal (typically $11/sample). If you would like the samples to be held longer than ACZ's stated policy or to be returned, please contact your Project Manager or Customer Service Representative for further details and associated costs. ACZ retains analytical raw data reports for ten years.

If you have any questions or other needs, please contact your Project Manager.

Inorganic Reference

Report Header Explanations

Batch	A distinct set of samples analyzed at a specific time
Found	Value of the QC Type of interest
Limit	Upper limit for RPD, in %.
Lower	Lower Recovery Limit, in % (except for LCSS, mg/Kg)
MDL	Method Detection Limit. Same as Minimum Reporting Limit. Allows for instrument and annual fluctuations.
PCN/SCN	A number assigned to reagents/standards to trace to the manufacturer's certificate of analysis
PQL	Practical Quantitation Limit, typically 5 times the MDL.
QC	True Value of the Control Sample or the amount added to the Spike
Rec	Recovered amount of the true value or spike added, in % (except for LCSS, mg/Kg)
RPD	Relative Percent Difference, calculation used for Duplicate QC Types
Upper	Upper Recovery Limit, in % (except for LCSS, mg/Kg)
Sample	Value of the Sample of interest

QC Sample Types

AS	Analytical Spike (Post Digestion)	*LCSWD*	Laboratory Control Sample - Water Duplicate
ASD	Analytical Spike (Post Digestion) Duplicate	*LFB*	Laboratory Fortified Blank
CCB	Continuing Calibration Blank	*LFM*	Laboratory Fortified Matrix
CCV	Continuing Calibration Verification standard	*LFMD*	Laboratory Fortified Matrix Duplicate
DUP	Sample Duplicate	*LRB*	Laboratory Reagent Blank
ICB	Initial Calibration Blank	*MS*	Matrix Spike
ICV	Initial Calibration Verification standard	*MSD*	Matrix Spike Duplicate
ICSAB	Inter-element Correction Standard - A plus B solutions	*PBS*	Prep Blank - Soil
LCSS	Laboratory Control Sample - Soil	*PBW*	Prep Blank - Water
LCSSD	Laboratory Control Sample - Soil Duplicate	*PQV*	Practical Quantitation Verification standard
LCSW	Laboratory Control Sample - Water	*SDL*	Serial Dilution

QC Sample Type Explanations

Blanks	Verifies that there is no or minimal contamination in the prep method or calibration procedure.
Control Samples	Verifies the accuracy of the method, including the prep procedure.
Duplicates	Verifies the precision of the instrument and/or method.
Spikes/Fortified Matrix	Determines sample matrix interferences, if any.
Standard	Verifies the validity of the calibration.

ACZ Qualifiers (Qual)

B	Analyte concentration detected at a value between MDL and PQL. The associated value is an estimated quantity.
H	Analysis exceeded method hold time. pH is a field test with an immediate hold time.
L	Target analyte response was below the laboratory defined negative threshold.
U	The material was analyzed for, but was not detected above the level of the associated value. The associated value is either the sample quantitation limit or the sample detection limit.

Comments

(1) QC results calculated from raw data. Results may vary slightly if the rounded values are used in the calculations.
(2) Soil, Sludge, and Plant matrices for Inorganic analyses are reported on a dry weight basis.
(3) Animal matrices for Inorganic analyses are reported on an "as received" basis.
(4) An asterisk in the "XQ" column indicates there is an extended qualifier and/or certification qualifier associated with the result.
(5) If the MDL equals the PQL or the MDL column is omitted, the PQL is the reporting limit.

		Carbon, total organic (TOC)	ASA No.9 29-2.2.4 Combustion/IR	Q6	Sample was received above recommended temperature.
			ASA No.9 29-2.2.4 Combustion/IR	ZQ	Analyte was not evaluated in the laboratory control standard. Either the analyte is not included in the scope of the analytical method or a commercial standard containing the analyte is not available.
	WG343478	Nitrate/Nitrite as N, soluble (Water)	M353.2 - Automated Cadmium Reduction	D1	Sample required dilution due to matrix.
			M353.2 - Automated Cadmium Reduction	HD	Analysis is outside the intended scope of the method, which does not provide hold time information for soil extracts. No hold time is observed for collection to extraction. The referenced method hold time is observed for extraction-to-analysis.
			M353.2 - Automated Cadmium Reduction	RA	Relative Percent Difference (RPD) was not used for data validation because the sample concentration is too low for accurate evaluation (< 10x MDL).
		Nitrite as N, soluble (Water)	M353.2 - Automated Cadmium Reduction	D1	Sample required dilution due to matrix.
			M353.2 - Automated Cadmium Reduction	HD	Analysis is outside the intended scope of the method, which does not provide hold time information for soil extracts. No hold time is observed for collection to extraction. The referenced method hold time is observed for extraction-to-analysis.
			M353.2 - Automated Cadmium Reduction	RA	Relative Percent Difference (RPD) was not used for data validation because the sample concentration is too low for accurate evaluation (< 10x MDL).
	WG343550	Nitrogen, ammonia (Water)	M350.1 - Automated Phenate	D1	Sample required dilution due to matrix.
			M350.1 - Automated Phenate	HD	Analysis is outside the intended scope of the method, which does not provide hold time information for soil extracts. No hold time is observed for collection to extraction. The referenced method hold time is observed for extraction-to-analysis.
			M350.1 - Automated Phenate	RA	Relative Percent Difference (RPD) was not used for data validation because the sample concentration is too low for accurate evaluation (< 10x MDL).
	WG344213	Nitrogen, total Kjeldahl	M351.2 - TKN by Block Digester	HC	Initial analysis within holding time. Reanalysis was past holding time, which was required due to a QC failure during the initial analysis.
			M351.2 - TKN by Block Digester	Q6	Sample was received above recommended temperature.
L11856-09	WG343997	Copper (1312)	M6010B ICP	RA	Relative Percent Difference (RPD) was not used for data validation because the sample concentration is too low for accurate evaluation (< 10x MDL).
	WG343723	Copper, total (3050)	M6010B ICP	M3	The spike recovery value is unusable since the analyte concentration in the sample is disproportionate to the spike level. The recovery of the associated control sample (LCS or LFB) was acceptable.
L11856-10	WG343997	Copper (1312)	M6010B ICP	RA	Relative Percent Difference (RPD) was not used for data validation because the sample concentration is too low for accurate evaluation (< 10x MDL).
	WG343723	Copper, total (3050)	M6010B ICP	M3	The spike recovery value is unusable since the analyte concentration in the sample is disproportionate to the spike level. The recovery of the associated control sample (LCS or LFB) was acceptable.

Inorganic Extended Qualifier Report

Freeport-McMoRan - Chino Mines Company

ACZ Project ID: ***L11856***

ACZ ID	WORKNUM	PARAMETER	METHOD	QUAL	DESCRIPTION
L11856-11	WG343997	Copper (1312)	M6010B ICP	RA	Relative Percent Difference (RPD) was not used for data validation because the sample concentration is too low for accurate evaluation (< 10x MDL).
	WG343723	Copper, total (3050)	M6010B ICP	M3	The spike recovery value is unusable since the analyte concentration in the sample is disproportionate to the spike level. The recovery of the associated control sample (LCS or LFB) was acceptable.
L11856-12	WG343997	Copper (1312)	M6010B ICP	RA	Relative Percent Difference (RPD) was not used for data validation because the sample concentration is too low for accurate evaluation (< 10x MDL).
	WG343723	Copper, total (3050)	M6010B ICP	M3	The spike recovery value is unusable since the analyte concentration in the sample is disproportionate to the spike level. The recovery of the associated control sample (LCS or LFB) was acceptable.
L11856-13	WG343997	Copper (1312)	M6010B ICP	RA	Relative Percent Difference (RPD) was not used for data validation because the sample concentration is too low for accurate evaluation (< 10x MDL).
	WG343723	Copper, total (3050)	M6010B ICP	M3	The spike recovery value is unusable since the analyte concentration in the sample is disproportionate to the spike level. The recovery of the associated control sample (LCS or LFB) was acceptable.
L11856-14	WG343997	Copper (1312)	M6010B ICP	RA	Relative Percent Difference (RPD) was not used for data validation because the sample concentration is too low for accurate evaluation (< 10x MDL).
	WG343723	Copper, total (3050)	M6010B ICP	M3	The spike recovery value is unusable since the analyte concentration in the sample is disproportionate to the spike level. The recovery of the associated control sample (LCS or LFB) was acceptable.
L11856-15	WG343997	Copper (1312)	M6010B ICP	RA	Relative Percent Difference (RPD) was not used for data validation because the sample concentration is too low for accurate evaluation (< 10x MDL).
	WG343723	Copper, total (3050)	M6010B ICP	M3	The spike recovery value is unusable since the analyte concentration in the sample is disproportionate to the spike level. The recovery of the associated control sample (LCS or LFB) was acceptable.

Soil Analysis

The following parameters are not offered for certification or are not covered by NELAC certificate #ACZ.

Carbon, total (TC)	ASA No.9 29-2.2.4 Combustion/IR
Carbon, total organic (TOC)	ASA No.9 29-2.2.4 Combustion/IR
pH, Saturated Paste	EPA 600/2-78-054, section 3.2.2
Solids, Percent	CLPSOW390, PART F, D-98

Wet Chemistry

The following parameters are not offered for certification or are not covered by NELAC certificate #ACZ.

Nitrate/Nitrite as N, soluble (Water)	M353.2 - Automated Cadmium Reduction
Nitrite as N, soluble (Water)	M353.2 - Automated Cadmium Reduction
Nitrogen, ammonia (Water)	M350.1 - Automated Phenate
Nitrogen, total Kjeldahl	M351.2 - TKN by Block Digester

Received By: ksj
Date Printed: 5/22/2013

Receipt Verification

	YES	NO	NA
1) Is a foreign soil permit included for applicable samples?			X
2) Is the Chain of Custody or other directive shipping papers present?	X		▨
3) Does this project require special handling procedures such as CLP protocol?			X
4) Are any samples NRC licensable material?			X
5) If samples are received past hold time, proceed with requested short hold time analyses?	X		
6) Is the Chain of Custody complete and accurate?	X		▨
7) Were any changes made to the Chain of Custody prior to ACZ receiving the samples?	X		▨

A change was made in the page 2 lines 3-6 and page 3 line 4 section prior to ACZ custody.

Samples/Containers

	YES	NO	NA
8) Are all containers intact and with no leaks?	X		▨
9) Are all labels on containers and are they intact and legible?	X		▨
10) Do the sample labels and Chain of Custody match for Sample ID, Date, and Time?	X		▨
11) For preserved bottle types, was the pH checked and within limits?			X
12) Is there sufficient sample volume to perform all requested work?	X		▨
13) Is the custody seal intact on all containers?			X
14) Are samples that require zero headspace acceptable?			X
15) Are all sample containers appropriate for analytical requirements?	X		▨
16) Is there an Hg-1631 trip blank present?			X
17) Is there a VOA trip blank present?			X
18) Were all samples received within hold time?	X		▨

Analytical Report

November 15, 2013

Report to:	Bill to:
Pam Pinson	Pam Pinson
Freeport-McMoRan - Chino Mines Company	Freeport-McMoRan - Chino Mines Company
PO Box 10	P.O. Box 13308
Bayard, NM 88023	Phoenix, AZ 85002-3308

cc: Matthew Barkley

Project ID: ZN000001M5
ACZ Project ID: L15301

Pam Pinson:

Enclosed are the analytical results for sample(s) submitted to ACZ Laboratories, Inc. (ACZ) on October 30, 2013. This project has been assigned to ACZ's project number, L15301. Please reference this number in all future inquiries.

All analyses were performed according to ACZ's Quality Assurance Plan. The enclosed results relate only to the samples received under L15301. Each section of this report has been reviewed and approved by the appropriate Laboratory Supervisor, or a qualified substitute.

Except as noted, the test results for the methods and parameters listed on ACZ's current NELAC certificate letter (#ACZ) meet all requirements of NELAC.

This report shall be used or copied only in its entirety. ACZ is not responsible for the consequences arising from the use of a partial report.

All samples and sub-samples associated with this project will be disposed of after December 15, 2013. If the samples are determined to be hazardous, additional charges apply for disposal (typically $11/sample). If you would like the samples to be held longer than ACZ's stated policy or to be returned, please contact your Project Manager or Customer Service Representative for further details and associated costs. ACZ retains analytical raw data reports for ten years.

If you have any questions or other needs, please contact your Project Manager.

Inorganic Reference

Report Header Explanations

Batch	A distinct set of samples analyzed at a specific time
Found	Value of the QC Type of interest
Limit	Upper limit for RPD, in %.
Lower	Lower Recovery Limit, in % (except for LCSS, mg/Kg)
MDL	Method Detection Limit. Same as Minimum Reporting Limit. Allows for instrument and annual fluctuations.
PCN/SCN	A number assigned to reagents/standards to trace to the manufacturer's certificate of analysis
PQL	Practical Quantitation Limit, typically 5 times the MDL.
QC	True Value of the Control Sample or the amount added to the Spike
Rec	Recovered amount of the true value or spike added, in % (except for LCSS, mg/Kg)
RPD	Relative Percent Difference, calculation used for Duplicate QC Types
Upper	Upper Recovery Limit, in % (except for LCSS, mg/Kg)
Sample	Value of the Sample of interest

QC Sample Types

AS	Analytical Spike (Post Digestion)	*LCSWD*	Laboratory Control Sample - Water Duplicate
ASD	Analytical Spike (Post Digestion) Duplicate	*LFB*	Laboratory Fortified Blank
CCB	Continuing Calibration Blank	*LFM*	Laboratory Fortified Matrix
CCV	Continuing Calibration Verification standard	*LFMD*	Laboratory Fortified Matrix Duplicate
DUP	Sample Duplicate	*LRB*	Laboratory Reagent Blank
ICB	Initial Calibration Blank	*MS*	Matrix Spike
ICV	Initial Calibration Verification standard	*MSD*	Matrix Spike Duplicate
ICSAB	Inter-element Correction Standard - A plus B solutions	*PBS*	Prep Blank - Soil
LCSS	Laboratory Control Sample - Soil	*PBW*	Prep Blank - Water
LCSSD	Laboratory Control Sample - Soil Duplicate	*PQV*	Practical Quantitation Verification standard
LCSW	Laboratory Control Sample - Water	*SDL*	Serial Dilution

QC Sample Type Explanations

Blanks	Verifies that there is no or minimal contamination in the prep method or calibration procedure.
Control Samples	Verifies the accuracy of the method, including the prep procedure.
Duplicates	Verifies the precision of the instrument and/or method.
Spikes/Fortified Matrix	Determines sample matrix interferences, if any.
Standard	Verifies the validity of the calibration.

ACZ Qualifiers (Qual)

B	Analyte concentration detected at a value between MDL and PQL. The associated value is an estimated quantity.
H	Analysis exceeded method hold time. pH is a field test with an immediate hold time.
L	Target analyte response was below the laboratory defined negative threshold.
U	The material was analyzed for, but was not detected above the level of the associated value. The associated value is either the sample quantitation limit or the sample detection limit.

Comments

(1) QC results calculated from raw data. Results may vary slightly if the rounded values are used in the calculations.
(2) Soil, Sludge, and Plant matrices for Inorganic analyses are reported on a dry weight basis.
(3) Animal matrices for Inorganic analyses are reported on an "as received" basis.
(4) An asterisk in the "XQ" column indicates there is an extended qualifier and/or certification qualifier associated with the result.
(5) If the MDL equals the PQL or the MDL column is omitted, the PQL is the reporting limit.

	Total Sulfur minus Sulfate	M600/2-78-054 3.2.4-MOD

Sample Receipt

Freeport-McMoRan - Chino Mines Company
ZN000001M5

ACZ Project ID: L15301
Date Received: 10/30/2013 10:02
Received By: mtb
Date Printed: 10/30/2013

Receipt Verification

	YES	NO	NA
1) Is a foreign soil permit included for applicable samples?			X
2) Is the Chain of Custody or other directive shipping papers present?	X		▨
3) Does this project require special handling procedures such as CLP protocol?			X
4) Are any samples NRC licensable material?			X
5) If samples are received past hold time, proceed with requested short hold time analyses?	X		
6) Is the Chain of Custody complete and accurate?	X		▨
7) Were any changes made to the Chain of Custody prior to ACZ receiving the samples?	X		▨

```
A change was made in the ID Line 6 section prior to ACZ
custody.
```

Samples/Containers

	YES	NO	NA
8) Are all containers intact and with no leaks?	X		▨
9) Are all labels on containers and are they intact and legible?	X		▨
10) Do the sample labels and Chain of Custody match for Sample ID, Date, and Time?	X		▨
11) For preserved bottle types, was the pH checked and within limits?			X
12) Is there sufficient sample volume to perform all requested work?	X		▨
13) Is the custody seal intact on all containers?			X
14) Are samples that require zero headspace acceptable?			X
15) Are all sample containers appropriate for analytical requirements?	X		▨
16) Is there an Hg-1631 trip blank present?			X
17) Is there a VOA trip blank present?			X
18) Were all samples received within hold time?	X		▨

```

Was ice present in the shipment container(s)?

```
No - Wet or gel ice was not present in the shipment container(s).
```

Client must contact an ACZ Project Manager if analysis should not proceed for samples received outside of their thermal preservation acceptance criteria.

If sample(s) received past holding time (HT), or if insufficient HT remains to complete analysis before expiration, shall ACZ proceed with requested short HT analyses? YES ☒ NO ☐
If "NO" then ACZ will contact client for further instruction. If neither "YES" nor "NO" is indicated, ACZ will proceed with the requested analyses, even if HT is expired, and data will be qualified.

Are samples for CO DW Compliance Monitoring? YES ☐
If yes, please include state forms. Results will be reported to PQL. NO ☒

REMARKS

Please send to Sheri Fling at URS for validation. Sieve all soil samples to <2 mm prior to analysis. Soil should be reported on a dry weight basis.
Methods:
pH - 9045C, Total Copper - 6010B
Please include sulfur forms for ABA

Please refer to ACZ's terms & conditions located on the reverse side of this COC.

Analytical Report

November 20, 2013

Report to:	Bill to:
Pam Pinson	Pam Pinson
Freeport-McMoRan - Chino Mines Company	Freeport-McMoRan - Chino Mines Company
PO Box 10	P.O. Box 13308
Bayard, NM 88023	Phoenix, AZ 85002-3308

cc: Matthew Barkley

Project ID: ZN000001M5
ACZ Project ID: L15302

Pam Pinson:

Enclosed are the analytical results for sample(s) submitted to ACZ Laboratories, Inc. (ACZ) on October 30, 2013. This project has been assigned to ACZ's project number, L15302. Please reference this number in all future inquiries.

All analyses were performed according to ACZ's Quality Assurance Plan. The enclosed results relate only to the samples received under L15302. Each section of this report has been reviewed and approved by the appropriate Laboratory Supervisor, or a qualified substitute.

Except as noted, the test results for the methods and parameters listed on ACZ's current NELAC certificate letter (#ACZ) meet all requirements of NELAC.

This report shall be used or copied only in its entirety. ACZ is not responsible for the consequences arising from the use of a partial report.

All samples and sub-samples associated with this project will be disposed of after December 20, 2013. If the samples are determined to be hazardous, additional charges apply for disposal (typically $11/sample). If you would like the samples to be held longer than ACZ's stated policy or to be returned, please contact your Project Manager or Customer Service Representative for further details and associated costs. ACZ retains analytical raw data reports for ten years.

If you have any questions or other needs, please contact your Project Manager.

Inorganic Reference

Report Header Explanations

Batch	A distinct set of samples analyzed at a specific time
Found	Value of the QC Type of interest
Limit	Upper limit for RPD, in %.
Lower	Lower Recovery Limit, in % (except for LCSS, mg/Kg)
MDL	Method Detection Limit. Same as Minimum Reporting Limit. Allows for instrument and annual fluctuations.
PCN/SCN	A number assigned to reagents/standards to trace to the manufacturer's certificate of analysis
PQL	Practical Quantitation Limit, typically 5 times the MDL.
QC	True Value of the Control Sample or the amount added to the Spike
Rec	Recovered amount of the true value or spike added, in % (except for LCSS, mg/Kg)
RPD	Relative Percent Difference, calculation used for Duplicate QC Types
Upper	Upper Recovery Limit, in % (except for LCSS, mg/Kg)
Sample	Value of the Sample of interest

QC Sample Types

AS	Analytical Spike (Post Digestion)	*LCSWD*	Laboratory Control Sample - Water Duplicate
ASD	Analytical Spike (Post Digestion) Duplicate	*LFB*	Laboratory Fortified Blank
CCB	Continuing Calibration Blank	*LFM*	Laboratory Fortified Matrix
CCV	Continuing Calibration Verification standard	*LFMD*	Laboratory Fortified Matrix Duplicate
DUP	Sample Duplicate	*LRB*	Laboratory Reagent Blank
ICB	Initial Calibration Blank	*MS*	Matrix Spike
ICV	Initial Calibration Verification standard	*MSD*	Matrix Spike Duplicate
ICSAB	Inter-element Correction Standard - A plus B solutions	*PBS*	Prep Blank - Soil
LCSS	Laboratory Control Sample - Soil	*PBW*	Prep Blank - Water
LCSSD	Laboratory Control Sample - Soil Duplicate	*PQV*	Practical Quantitation Verification standard
LCSW	Laboratory Control Sample - Water	*SDL*	Serial Dilution

QC Sample Type Explanations

Blanks	Verifies that there is no or minimal contamination in the prep method or calibration procedure.
Control Samples	Verifies the accuracy of the method, including the prep procedure.
Duplicates	Verifies the precision of the instrument and/or method.
Spikes/Fortified Matrix	Determines sample matrix interferences, if any.
Standard	Verifies the validity of the calibration.

ACZ Qualifiers (Qual)

B	Analyte concentration detected at a value between MDL and PQL. The associated value is an estimated quantity.
H	Analysis exceeded method hold time. pH is a field test with an immediate hold time.
L	Target analyte response was below the laboratory defined negative threshold.
U	The material was analyzed for, but was not detected above the level of the associated value. The associated value is either the sample quantitation limit or the sample detection limit.

Method References

Comments

(1) QC results calculated from raw data. Results may vary slightly if the rounded values are used in the calculations.
(2) Soil, Sludge, and Plant matrices for Inorganic analyses are reported on a dry weight basis.
(3) Animal matrices for Inorganic analyses are reported on an "as received" basis.
(4) An asterisk in the "XQ" column indicates there is an extended qualifier and/or certification qualifier associated with the result.
(5) If the MDL equals the PQL or the MDL column is omitted, the PQL is the reporting limit.

Sample Receipt

Freeport-McMoRan - Chino Mines Company
ZN000001M5

ACZ Project ID: L15302
Date Received: 10/30/2013 10:04
Received By: mtb
Date Printed: 10/30/2013

Receipt Verification

	YES	NO	NA
1) Is a foreign soil permit included for applicable samples?			X
2) Is the Chain of Custody or other directive shipping papers present?	X		▨
3) Does this project require special handling procedures such as CLP protocol?			X
4) Are any samples NRC licensable material?			X
5) If samples are received past hold time, proceed with requested short hold time analyses?	X		
6) Is the Chain of Custody complete and accurate?	X		▨
7) Were any changes made to the Chain of Custody prior to ACZ receiving the samples?	X		▨

```
A change was made in the ID Lines 4-6 section prior to ACZ
custody.
```

Samples/Containers

	YES	NO	NA
8) Are all containers intact and with no leaks?	X		▨
9) Are all labels on containers and are they intact and legible?	X		▨
10) Do the sample labels and Chain of Custody match for Sample ID, Date, and Time?	X		▨
11) For preserved bottle types, was the pH checked and within limits?			X
12) Is there sufficient sample volume to perform all requested work?	X		▨
13) Is the custody seal intact on all containers?			X
14) Are samples that require zero headspace acceptable?			X
15) Are all sample containers appropriate for analytical requirements?	X		▨
16) Is there an Hg-1631 trip blank present?			X
17) Is there a VOA trip blank present?			X
18) Were all samples received within hold time?	X		▨

Chain of Custody Related Remarks

Client Contact Remarks

Shipping Containers

```
Cooler Id      Temp (°C)      Rad (µR/Hr)      Custody Seal Intact?
---------      ---------      -----------      --------------------
4057           10.8           13               Yes
NA18647        10.6           15               N/A
```

Was ice present in the shipment container(s)?

```
No - Wet or gel ice was not present in the shipment container(s).
```

Client must contact an ACZ Project Manager if analysis should not proceed for samples received outside of their thermal preservation acceptance criteria.

If sample(s) received past holding time (HT), or if insufficient HT remains to complete analysis before expiration, shall ACZ proceed with requested short HT analyses? YES ☒ NO ☐
If "NO" then ACZ will contact client for further instruction. If neither "YES" nor "NO" is indicated, ACZ will proceed with the requested analyses, even if HT is expired, and data will be qualified.

Are samples for CO DW Compliance Monitoring? YES ☐
If yes, please include state forms. Results will be reported to PQL. NO ☒

Pam Pinson:

Enclosed are the analytical results for sample(s) submitted to ACZ Laboratories, Inc. (ACZ) on October 30, 2013. This project has been assigned to ACZ's project number, L15303. Please reference this number in all future inquiries.

All analyses were performed according to ACZ's Quality Assurance Plan. The enclosed results relate only to the samples received under L15303. Each section of this report has been reviewed and approved by the appropriate Laboratory Supervisor, or a qualified substitute.

Except as noted, the test results for the methods and parameters listed on ACZ's current NELAC certificate letter (#ACZ) meet all requirements of NELAC.

This report shall be used or copied only in its entirety. ACZ is not responsible for the consequences arising from the use of a partial report.

All samples and sub-samples associated with this project will be disposed of after December 13, 2013. If the samples are determined to be hazardous, additional charges apply for disposal (typically $11/sample). If you would like the samples to be held longer than ACZ's stated policy or to be returned, please contact your Project Manager or Customer Service Representative for further details and associated costs. ACZ retains analytical raw data reports for ten years.

If you have any questions or other needs, please contact your Project Manager.

Inorganic Reference

Report Header Explanations

Batch	A distinct set of samples analyzed at a specific time
Found	Value of the QC Type of interest
Limit	Upper limit for RPD, in %.
Lower	Lower Recovery Limit, in % (except for LCSS, mg/Kg)
MDL	Method Detection Limit. Same as Minimum Reporting Limit. Allows for instrument and annual fluctuations.
PCN/SCN	A number assigned to reagents/standards to trace to the manufacturer's certificate of analysis
PQL	Practical Quantitation Limit, typically 5 times the MDL.
QC	True Value of the Control Sample or the amount added to the Spike
Rec	Recovered amount of the true value or spike added, in % (except for LCSS, mg/Kg)
RPD	Relative Percent Difference, calculation used for Duplicate QC Types
Upper	Upper Recovery Limit, in % (except for LCSS, mg/Kg)
Sample	Value of the Sample of interest

QC Sample Types

AS	Analytical Spike (Post Digestion)	*LCSWD*	Laboratory Control Sample - Water Duplicate
ASD	Analytical Spike (Post Digestion) Duplicate	*LFB*	Laboratory Fortified Blank
CCB	Continuing Calibration Blank	*LFM*	Laboratory Fortified Matrix
CCV	Continuing Calibration Verification standard	*LFMD*	Laboratory Fortified Matrix Duplicate
DUP	Sample Duplicate	*LRB*	Laboratory Reagent Blank
ICB	Initial Calibration Blank	*MS*	Matrix Spike
ICV	Initial Calibration Verification standard	*MSD*	Matrix Spike Duplicate
ICSAB	Inter-element Correction Standard - A plus B solutions	*PBS*	Prep Blank - Soil
LCSS	Laboratory Control Sample - Soil	*PBW*	Prep Blank - Water
LCSSD	Laboratory Control Sample - Soil Duplicate	*PQV*	Practical Quantitation Verification standard
LCSW	Laboratory Control Sample - Water	*SDL*	Serial Dilution

QC Sample Type Explanations

Blanks	Verifies that there is no or minimal contamination in the prep method or calibration procedure.
Control Samples	Verifies the accuracy of the method, including the prep procedure.
Duplicates	Verifies the precision of the instrument and/or method.
Spikes/Fortified Matrix	Determines sample matrix interferences, if any.
Standard	Verifies the validity of the calibration.

ACZ Qualifiers (Qual)

B	Analyte concentration detected at a value between MDL and PQL. The associated value is an estimated quantity.
H	Analysis exceeded method hold time. pH is a field test with an immediate hold time.
L	Target analyte response was below the laboratory defined negative threshold.
U	The material was analyzed for, but was not detected above the level of the associated value. The associated value is either the sample quantitation limit or the sample detection limit.

Method References

Comments

(1) QC results calculated from raw data. Results may vary slightly if the rounded values are used in the calculations.
(2) Soil, Sludge, and Plant matrices for Inorganic analyses are reported on a dry weight basis.
(3) Animal matrices for Inorganic analyses are reported on an "as received" basis.
(4) An asterisk in the "XQ" column indicates there is an extended qualifier and/or certification qualifier associated with the result.
(5) If the MDL equals the PQL or the MDL column is omitted, the PQL is the reporting limit.

Received By: mtb
Date Printed: 10/30/2013

Receipt Verification

	YES	NO	NA
1) Is a foreign soil permit included for applicable samples?			X
2) Is the Chain of Custody or other directive shipping papers present?	X		
3) Does this project require special handling procedures such as CLP protocol?			X
4) Are any samples NRC licensable material?			X
5) If samples are received past hold time, proceed with requested short hold time analyses?	X		
6) Is the Chain of Custody complete and accurate?		X	
`The date/time was not present on the sample containers or on the COC. The "Relinquished By" date was used to enter the samples.`			
7) Were any changes made to the Chain of Custody prior to ACZ receiving the samples?	X		
`A change was made in the ID Lines 4-6 section prior to ACZ custody.`			

Samples/Containers

	YES	NO	NA
8) Are all containers intact and with no leaks?	X		
9) Are all labels on containers and are they intact and legible?	X		
10) Do the sample labels and Chain of Custody match for Sample ID, Date, and Time?	X		
11) For preserved bottle types, was the pH checked and within limits?	X		
12) Is there sufficient sample volume to perform all requested work?	X		
13) Is the custody seal intact on all containers?			X
14) Are samples that require zero headspace acceptable?			X
15) Are all sample containers appropriate for analytical requirements?	X		
16) Is there an Hg-1631 trip blank present?			X
17) Is there a VOA trip blank present?			X
18) Were all samples received within hold time?	X		

Chain of Custody Related Remarks

Client Contact Remarks

Shipping Containers

Cooler Id	Temp (°C)	Rad (µR/Hr)	Custody Seal Intact?
4057	10.8	13	Yes

Was ice present in the shipment container(s)?

`No - Wet or gel ice was not present in the shipment container(s).`

If sample(s) received past holding time (HT), or if insufficient HT remains to complete analysis before expiration, shall ACZ proceed with requested short HT analyses? YES ☒ NO ☐

If "NO" then ACZ will contact client for further instruction. If neither "YES" nor "NO" is indicated, ACZ will proceed with the requested analyses, even if HT is expired, and data will be qualified.

Are samples for CO DW Compliance Monitoring? YES ☐ NO ☒

If yes, please include state forms. Results will be reported to PQL.

Inorganic Reference

Report Header Explanations

Batch	A distinct set of samples analyzed at a specific time
Found	Value of the QC Type of interest
Limit	Upper limit for RPD, in %.
Lower	Lower Recovery Limit, in % (except for LCSS, mg/Kg)
MDL	Method Detection Limit. Same as Minimum Reporting Limit. Allows for instrument and annual fluctuations.
PCN/SCN	A number assigned to reagents/standards to trace to the manufacturer's certificate of analysis
PQL	Practical Quantitation Limit, typically 5 times the MDL.
QC	True Value of the Control Sample or the amount added to the Spike
Rec	Recovered amount of the true value or spike added, in % (except for LCSS, mg/Kg)
RPD	Relative Percent Difference, calculation used for Duplicate QC Types
Upper	Upper Recovery Limit, in % (except for LCSS, mg/Kg)
Sample	Value of the Sample of interest

QC Sample Types

AS	Analytical Spike (Post Digestion)	*LCSWD*	Laboratory Control Sample - Water Duplicate
ASD	Analytical Spike (Post Digestion) Duplicate	*LFB*	Laboratory Fortified Blank
CCB	Continuing Calibration Blank	*LFM*	Laboratory Fortified Matrix
CCV	Continuing Calibration Verification standard	*LFMD*	Laboratory Fortified Matrix Duplicate
DUP	Sample Duplicate	*LRB*	Laboratory Reagent Blank
ICB	Initial Calibration Blank	*MS*	Matrix Spike
ICV	Initial Calibration Verification standard	*MSD*	Matrix Spike Duplicate
ICSAB	Inter-element Correction Standard - A plus B solutions	*PBS*	Prep Blank - Soil
LCSS	Laboratory Control Sample - Soil	*PBW*	Prep Blank - Water
LCSSD	Laboratory Control Sample - Soil Duplicate	*PQV*	Practical Quantitation Verification standard
LCSW	Laboratory Control Sample - Water	*SDL*	Serial Dilution

QC Sample Type Explanations

Blanks	Verifies that there is no or minimal contamination in the prep method or calibration procedure.
Control Samples	Verifies the accuracy of the method, including the prep procedure.
Duplicates	Verifies the precision of the instrument and/or method.
Spikes/Fortified Matrix	Determines sample matrix interferences, if any.
Standard	Verifies the validity of the calibration.

ACZ Qualifiers (Qual)

B	Analyte concentration detected at a value between MDL and PQL. The associated value is an estimated quantity.
H	Analysis exceeded method hold time. pH is a field test with an immediate hold time.
L	Target analyte response was below the laboratory defined negative threshold.
U	The material was analyzed for, but was not detected above the level of the associated value. The associated value is either the sample quantitation limit or the sample detection limit.

Method References

Comments

(1) QC results calculated from raw data. Results may vary slightly if the rounded values are used in the calculations.
(2) Soil, Sludge, and Plant matrices for Inorganic analyses are reported on a dry weight basis.
(3) Animal matrices for Inorganic analyses are reported on an "as received" basis.
(4) An asterisk in the "XQ" column indicates there is an extended qualifier and/or certification qualifier associated with the result.
(5) If the MDL equals the PQL or the MDL column is omitted, the PQL is the reporting limit.

For a complete list of ACZ's Extended Qualifiers, please click: http://www.acz.com/public/extquallist.pdf

ACZ ID	WORKNUM	PARAMETER	METHOD	QUAL	DESCRIPTION
L15304-14	WG354618	Calcium, total (3050)	M6010B ICP	M2	Matrix spike recovery was low, the recovery of the associated control sample (LCS or LFB) was acceptable.
	WG354686	Copper (1312)	M6010B ICP	RA	Relative Percent Difference (RPD) was not used for data validation because the sample concentration is too low for accurate evaluation (< 10x MDL).
	WG354618	Copper, total (3050)	M6010B ICP	M3	The spike recovery value is unusable since the analyte concentration in the sample is disproportionate to the spike level. The recovery of the associated control sample (LCS or LFB) was acceptable.
	WG354626	Carbon, total (TC)	ASA No.9 29-2.2.4 Combustion/IR	Q6	Sample was received above recommended temperature.
		Carbon, total organic (TOC)	ASA No.9 29-2.2.4 Combustion/IR	Q6	Sample was received above recommended temperature.
			ASA No.9 29-2.2.4 Combustion/IR	ZQ	Analyte was not evaluated in the laboratory control standard. Either the analyte is not included in the scope of the analytical method or a commercial standard containing the analyte is not available.
	WG354762	Nitrate/Nitrite as N, soluble (Water)	M353.2 - Automated Cadmium Reduction	HD	Analysis is outside the intended scope of the method, which does not provide hold time information for soil extracts. No hold time is observed for collection to extraction. The referenced method hold time is observed for extraction-to-analysis.
			M353.2 - Automated Cadmium Reduction	RA	Relative Percent Difference (RPD) was not used for data validation because the sample concentration is too low for accurate evaluation (< 10x MDL).
		Nitrite as N, soluble (Water)	M353.2 - Automated Cadmium Reduction	HD	Analysis is outside the intended scope of the method, which does not provide hold time information for soil extracts. No hold time is observed for collection to extraction. The referenced method hold time is observed for extraction-to-analysis.
			M353.2 - Automated Cadmium Reduction	RA	Relative Percent Difference (RPD) was not used for data validation because the sample concentration is too low for accurate evaluation (< 10x MDL).
	WG354803	Nitrogen, ammonia (Water)	M350.1 - Automated Phenate	DD	Sample required dilution due to matrix color or odor.
			M350.1 - Automated Phenate	RA	Relative Percent Difference (RPD) was not used for data validation because the sample concentration is too low for accurate evaluation (< 10x MDL).
	WG354723	Nitrogen, total Kjeldahl	M351.2 - TKN by Block Digester	M2	Matrix spike recovery was low, the recovery of the associated control sample (LCS or LFB) was acceptable.
			M351.2 - TKN by Block Digester	Q6	Sample was received above recommended temperature.

ACZ ID	WORKNUM	PARAMETER	METHOD	QUAL	DESCRIPTION
L15304-15	WG354650	Calcium, total (3050)	M6010B ICP	MA	Recovery for either the spike or spike duplicate was outside of the acceptance limits; the RPD was within the acceptance limits.
	WG354686	Copper (1312)	M6010B ICP	RA	Relative Percent Difference (RPD) was not used for data validation because the sample concentration is too low for accurate evaluation (< 10x MDL).
	WG354618	Copper, total (3050)	M6010B ICP	M3	The spike recovery value is unusable since the analyte concentration in the sample is disproportionate to the spike level. The recovery of the associated control sample (LCS or LFB) was acceptable.
	WG354626	Carbon, total (TC)	ASA No.9 29-2.2.4 Combustion/IR	Q6	Sample was received above recommended temperature.

	WG354618	Copper, total (3050)	M6010B ICP	M3	The spike recovery value is unusable since the analyte concentration in the sample is disproportionate to the spike level. The recovery of the associated control sample (LCS or LFB) was acceptable.
L15304-19	WG354686	Copper (1312)	M6010B ICP	RA	Relative Percent Difference (RPD) was not used for data validation because the sample concentration is too low for accurate evaluation (< 10x MDL).
	WG354618	Copper, total (3050)	M6010B ICP	M3	The spike recovery value is unusable since the analyte concentration in the sample is disproportionate to the spike level. The recovery of the associated control sample (LCS or LFB) was acceptable.
L15304-20	WG354686	Copper (1312)	M6010B ICP	RA	Relative Percent Difference (RPD) was not used for data validation because the sample concentration is too low for accurate evaluation (< 10x MDL).
	WG354618	Copper, total (3050)	M6010B ICP	M3	The spike recovery value is unusable since the analyte concentration in the sample is disproportionate to the spike level. The recovery of the associated control sample (LCS or LFB) was acceptable.

Certification Qualifiers

Soil Analysis

The following parameters are not offered for certification or are not covered by AZ certificate #AZ0102.

Carbon, total (TC)	ASA No.9 29-2.2.4 Combustion/IR
Carbon, total organic (TOC)	ASA No.9 29-2.2.4 Combustion/IR
pH, Saturated Paste	EPA 600/2-78-054, section 3.2.2
Solids, Percent	CLPSOW390, PART F, D-98

The following parameters are not offered for certification or are not covered by NELAC certificate #ACZ.

Carbon, total (TC)	ASA No.9 29-2.2.4 Combustion/IR
Carbon, total organic (TOC)	ASA No.9 29-2.2.4 Combustion/IR
pH, Saturated Paste	EPA 600/2-78-054, section 3.2.2
Solids, Percent	CLPSOW390, PART F, D-98

Wet Chemistry

The following parameters are not offered for certification or are not covered by AZ certificate #AZ0102.

Nitrate/Nitrite as N, soluble (Water)	M353.2 - Automated Cadmium Reduction
Nitrite as N, soluble (Water)	M353.2 - Automated Cadmium Reduction
Nitrogen, ammonia (Water)	M350.1 - Automated Phenate
Nitrogen, total Kjeldahl	M351.2 - TKN by Block Digester

The following parameters are not offered for certification or are not covered by NELAC certificate #ACZ.

Nitrate/Nitrite as N, soluble (Water)	M353.2 - Automated Cadmium Reduction
Nitrite as N, soluble (Water)	M353.2 - Automated Cadmium Reduction
Nitrogen, ammonia (Water)	M350.1 - Automated Phenate
Nitrogen, total Kjeldahl	M351.2 - TKN by Block Digester

ACZ Project ID: L15304
Date Received: 10/30/2013 10:18
Received By: mtb
Date Printed: 10/30/2013

Receipt Verification

	YES	NO	NA
1) Is a foreign soil permit included for applicable samples?			X
2) Is the Chain of Custody or other directive shipping papers present?	X		
3) Does this project require special handling procedures such as CLP protocol?			X
4) Are any samples NRC licensable material?			X
5) If samples are received past hold time, proceed with requested short hold time analyses?	X		
6) Is the Chain of Custody complete and accurate?	X		
7) Were any changes made to the Chain of Custody prior to ACZ receiving the samples?		X	

Samples/Containers

	YES	NO	NA
8) Are all containers intact and with no leaks?	X		
9) Are all labels on containers and are they intact and legible?	X		
10) Do the sample labels and Chain of Custody match for Sample ID, Date, and Time?	X		
11) For preserved bottle types, was the pH checked and within limits?			X
12) Is there sufficient sample volume to perform all requested work?	X		
13) Is the custody seal intact on all containers?			X
14) Are samples that require zero headspace acceptable?			X
15) Are all sample containers appropriate for analytical requirements?	X		
16) Is there an Hg-1631 trip blank present?			X
17) Is there a VOA trip blank present?			X
18) Were all samples received within hold time?	X

Phoenix, AZ 85002-3308

Project ID: ZN000001M5
ACZ Project ID: L15305

Pam Pinson:

Enclosed are the analytical results for sample(s) submitted to ACZ Laboratories, Inc. (ACZ) on October 30, 2013. This project has been assigned to ACZ's project number, L15305. Please reference this number in all future inquiries.

All analyses were performed according to ACZ's Quality Assurance Plan. The enclosed results relate only to the samples received under L15305. Each section of this report has been reviewed and approved by the appropriate Laboratory Supervisor, or a qualified substitute.

Except as noted, the test results for the methods and parameters listed on ACZ's current NELAC certificate letter (#ACZ) meet all requirements of NELAC.

This report shall be used or copied only in its entirety. ACZ is not responsible for the consequences arising from the use of a partial report.

All samples and sub-samples associated with this project will be disposed of after December 22, 2013. If the samples are determined to be hazardous, additional charges apply for disposal (typically $11/sample). If you would like the samples to be held longer than ACZ's stated policy or to be returned, please contact your Project Manager or Customer Service Representative for further details and associated costs. ACZ retains analytical raw data reports for ten years.

If you have any questions or other needs, please contact your Project Manager.

S. Habermehl

Scott Habermehl has reviewed
and approved this report.

Freeport-McMoRan - Chino Mines Company

November 22, 2013

Project ID: ZN000001M5
ACZ Project ID: L15305

Sample Receipt

ACZ Laboratories, Inc. (ACZ) received 20 soil samples from Freeport-McMoRan - Chino Mines Company on October 30, 2013. The samples were received in good condition. Upon receipt, the sample custodian removed the samples from the cooler, inspected the contents, and logged the samples into ACZ's computerized Laboratory Information Management System (LIMS). The samples were assigned ACZ LIMS project number L15305. The custodian verified the sample information entered into the computer against the chain of custody (COC) forms and sample bottle labels.

Holding Times

All analyses were performed within EPA recommended holding times.

Sample Analysis

These samples were analyzed for inorganic parameters. The individual methods are referenced on both, the ACZ invoice and the analytical reports. The extended qualifier reports may contain footnotes qualifying specific elements due to QC failures. In addition the following has been noted with this specific project:

The following modifications have been made to the SPLP Copper analysis (N1):

1) The soil to solution ratio was reduced to better simulate soils wetted by rainfall. A ratio of 1:5 soil:solution should be used for chemical analysis.

2) A 0.01 M $CaCl_2$ lixiviant was used instead of deionized water to better simulate the ionic strength of soil solutions (after Sauve et al. 1995); and

3) No adjustment to the initial pH of the soil solution to 5, as is commonly done in the Standard Method 1312 implementation. This step is taken to help ensure that the pH of the soil solution is due to the elements of the solution, not an outside source of acid.
